

FIGURE 12.51. Digitally reconstructed AP **A:** and lateral **B:** radiographs with associated contoured targets including the pelvic lymph nodes and uterus/cervix/parametria and vagina. Note the multileaf collimator leaves defining the field shape in accordance with coverage of the targets of interest.

horizontal line, parallel to the treatment couch that divides the mid-rectum and intersects the sacrum between the second and third sacral segments (S2–3 interspace), and the anterior border by a horizontal line, parallel to the treatment couch from the anteroinferior lip of L5 to the anterior aspect of the pubic symphysis (235). These “standard” lateral fields are too narrow. For the lateral fields, careful consideration needs to be given to the anterior border to include the external iliac nodes. Based on lymphangiography, Pendlebury et al. found that to cover the external iliac nodes, the anterior border of the lateral field was sometimes as much as 2 cm anterior to the pubic symphysis (231), which was later confirmed by Bonin et al. (229). Chun et al. found that based on CT definition of the external iliac lymph nodes, when using standard lateral fields, only 50% of the patients studied had adequate coverage of these nodes (230). Additionally, the anterior border must also be drawn to include the entire uterus, given the interconnecting lymphatics of the uterus and cervix and the possibility of lower uterine segment/endometrial extension (Fig. 12.52) (227,232,236). Enlargement of the uterine fundus by the presence of hematomata or massive fundal extension of cancer can displace the fundus anteriorly and cephalad, as can an anteverted or retroverted uterus (232,237,243). The prone position may accentuate this displacement (234,236). The anterior field border should be based on CT or MRI delineation of the tumor and/or normal anatomical variants to avoid underdosing of these structures (230,232,234,235,237,242,243). The posterior border of the lateral fields must be designed carefully. Based on intraoperative findings, Greer et al. showed that the cardinal and uterosacral ligaments extend posterior to the rectum and sigmoid in their attachments to the sacrum. As part of the parametria, these tissues often contain nodes, even in early disease (IB and II, 22.5%) or are involved by direct extension and need to be covered in most patients by including the entire sacrum in the lateral fields (239). If there is uterosacral ligament involvement, it is especially important to include the entire sacrum in the lateral fields, although some institutions will use this as a criterion for AP–PA fields alone (226). The internal iliac lymph nodes can also lie very close to the rectum and splitting of the rectum can result in a marginal miss of these nodes (Fig. 12.53) (228). For posterior cervical lesions, there can also be direct extension to the superior rectal nodes or sacral lymph nodes (224). Tumor can also

extend directly around the rectum. Kim et al. found that the most common site of an inadequate margin was near the portion of the lateral field blocking the rectum. On CT, it was found that tumor often fell along the lateral aspect of the rectum. The second most common site of inadequate margin was the posterior border at the S2–3 interspace (232). Zunino et al. also found inadequate posterior border margins when the uterus was both retroverted and anteverted (Fig. 12.52) (237). The reason for narrow lateral fields is typically concern over the rectum and the small bowel. Russell et al. have included the entire sacrum in the lateral fields of all patients with cervical cancer treated at their institution, and they have reported no increase in acute or late morbidity. When present, all rectal injuries observed have been on the anterior rectal wall due to the proximity of the implants used in the definitive management of these patients (235). Greer et al. also reported no increase in late rectal complications when including the entire sacrum in the field (239). It may also be a mistake to avoid the chance of a marginal miss by treating just with anterior and posterior fields, as in most cases some of the small bowel can be omitted from the lateral fields when using imaged-based planning (235). Gerstner et al. found that by using beam’s eye view–based 3D treatment planning, though the rectal volume treated increased to avoid a marginal miss, there was an overall reduction in the lateral field treatment volume as compared to standard treatment fields due to beam shaping to exclude portions of the bladder and small bowel and bladder distention (242). MRI has been found to be an invaluable tool for delineating normal anatomy and the extent of cervical tumor involvement because of its superior soft-tissue contrast when compared to CT. MRI also allows direct imaging in sagittal, coronal, and transverse plains (237). Sagittal MRI images are exceedingly helpful in designing radiation fields (Fig. 12.52). Design of the anterior and posterior borders of the lateral fields can be especially influenced by these images (234–237,243). Thomas et al. performed MRI rather than CT in the treatment position, and found better delineation of the tumor volume due to the superior contrast resolution (236). Lymphangiograms are very helpful in defining the location and architecture of lymph nodes when designing radiation fields, and are especially helpful in designing the lateral fields and subsequent nodal boost fields (229,231,237,244). They do not routinely image the internal iliac lymph nodes, although sometimes these will fill

FIGURE 12.52. (A–B): Traditional lateral fields are superimposed on sagittal MRI scans to evaluate target coverage with traditional fields. Note in **A**: that the traditional lateral fields would not completely cover the uterine fundus, and that in **B**: the traditional lateral field would cut through cervical tumor within the anteverted uterus.

in a retrograde manner. Unfortunately, lymphangiography is available at only a few institutions due to the fact that it is time consuming for both the radiologist and patient, and fewer radiologists are trained in such procedures (229). Positron emission tomography (PET)/CT scans have largely replaced lymphangiograms at most institutions with Medicare approval in 2005 and can detect involved pelvic and paraaortic lymph nodes better than CT alone (245–248). PET does not rely on lymph node size alone, unlike CT; rather, it relies on metabolic alterations for detection of disease. PET has better accuracy than can be achieved with CT or MRI with a sensitivity of 85% to 90%, a specificity of 95% to 100%, and overall accuracy of 90% to 95%. Nodes as small as 6 mm can be imaged with PET, providing information to guide therapy and predict outcome.

Midline Blocks

Midline blocks are used at variable points in time at many institutions (Fig. 12.47). It is important to understand when the midline block is placed as this will influence the HDR fraction size. Higher whole pelvis doses can be utilized without a midline block (162,163), but the HDR doses have to be appropriately reduced. HDR and external beam fractions should not be given on the same day. Use of midline blocks is controversial as there can be an increased risk of rectosigmoid, bladder, and small bowel complications if careful attention is not given to tracking and limiting the total dose in these OAR (254–256).

A midline block may be used during external beam to avoid regions of excessive dose adjacent to the brachytherapy implant and to deliver an adequate dose to potential tumor-bearing regions outside of the implant. When using a midline block early in the treatment course, more reliance is placed on the extremely complex match between the intracavitary system and the edge of the midline block. Some institutions customize the midline shield for each patient by defining the block edges as the contour of the isodose line passing through point A (249), or the 50% isodose line. Other institutions further customize this by stepping or altering the block thickness at specific isodose level intervals to achieve a dose “feathering” effect between the external beam and brachytherapy doses. The step-wedge or variable thickness transmission block used at Mallinckrodt (MIR) was initially designed to correspond to the various isodoses of the intracavitary insertions with various tandem and ovoid configurations (141,250,251). Over time, a customized step-wedge was not fabricated for each patient, but a number of standard prefabricated sizes were made available for repeated use. Several other institutions have published use of customized step-wedge midline blocks based on individual implants (252). Most institutions use rectangular blocks 4 to 5 cm in width rather than production of blocks based on the isodose distributions (Fig. 12.47) (249,253).

There are some important safety issues when using midline blocks (254–256). The midline block position should be based on films with similar isocenters. If patients receive external beam irradiation in the prone position, it may be wise to simulate them in the supine position for their parametrial boosts so that they are in the same position as they are for their implants. Midline blocks can be positioned to account for applicator deviation. Wolfson et al. found that most institutions using the standard rectangular midline blocks align the superior–inferior central axis of the block along the midplane of the patient’s pelvis, while those using customized midline blocks usually align the midline block along the axis of the tandem (249). Aligning along the midplane of the patient can be problematic if the tandem is deviated. The step-wedge corrects for the lateral gradient of the intracavitary system and not the rapid dose gradient anterior and posterior to the plane of the implant or for variations in the positions of the implants. The contribution of scattered radiation may increase the dose under narrow midline blocks, which

may exceed the anticipated 5% of the primary pelvic dose when using a 5 to 6 half-value layer (HVL) midline block. Midline blocks that are too narrow may not adequately shield the bladder and rectosigmoid given their ability to move in and out of the blocked field. Filling and emptying of these organs may also alter their position relative to the block. Eifel et al. point out that the distance between the distal ureters is usually 4 to 5 cm. A narrow block may fail to shield a portion of the ureters during external beam (257). Reviewing the M.D. Anderson experience, Eifel et al. detected an increase in complications in patients with midline blocks (4 cm) used throughout the course of external beam. Since the ureters are typically 2 to 3 cm from midline, the explanation for the ureteral stenosis could have been an overlap between the external beam fields and the high-dose region of the intracavitary implants (257). A margin of 0.5 cm lateral to the lateral ovoid surface is recommended in designing the width of the midline block for each patient to protect the implanted volume. If the intracavitary system is broad, a wide midline block may potentially shield the external iliac lymph nodes. If tissues immediately adjacent to the colpostats and tandem tip are not shielded, portions of the ileocecal junction and rectosigmoid may be overdosed (258,259). Huang et al. recommended avoiding a combination of parametrial boost doses of ≥ 54 Gy and a cumulative rectal biologically effective dose (CRBED) ≥ 100 Gy₃ to decrease the risk of radiation-induced bowel complications (259). Chun et al. also found increasing rectal complications with parametrial boosts >55 Gy (257). When a midline block is inserted prior to 40 Gy, it should not extend to the top of the field since it will shield the common iliac and presacral lymph nodes, which will be underdosed (249). Kuipers notes that the uterus can be displaced cranially toward the sigmoid during intracavitary irradiation because of vaginal packing. It may be important to make the midline block high enough to protect the sigmoid so that it does not receive further radiation during external beam (260). The inferior edge of the midline block should be coincident with the caudal aspect of the whole pelvis fields to avoid overdosage of the distal vagina (249). When there is suspicion of uterosacral ligament involvement, it is safer to avoid early placement of the midline block, which will shield disease lying posterior to the implant (226). Due to concern over rectal tolerance, the rectum is shielded after a certain amount of external beam radiation therapy, which can block tumor in the perirectal area and uterosacral space. The geometric configuration of the intracavitary implant emphasizes lateral rather than posterior coverage and does not effectively treat the perirectal and uterosacral space effectively. This can lead to underdosing of tissues in this area and an increased risk of central recurrence. Higher whole pelvis external beam doses, interstitial implantation, or addition of a supplemental posterior oblique external beam boost may offer ways to compensate dose in this area (226). Given the potential for risk, some would advocate abandoning the midline block in favor of other options (254–256). As there may be some disparity in implant position if multiple fractions are used over time, such as with HDR, it is necessary to reassess the midline block configuration after each implant (261).

Parametrial/Nodal Boosting in Cervical Cancer

Parametrial boosting is often recommended for patients with bulky parametrial or sidewall disease, after completion of the whole pelvis field and midline block fields, as the parametria are a common site of failure. The need for boosting is usually based on the status of disease regression following whole pelvis irradiation. MRI may be helpful in making this assessment both before and during radiation. Mayr et al. found MRI imaging useful in the localization of parametrial tumor extension and enlarged their parametrial boost fields based on these MRI

images to include the disease and exclude small bowel (234). Logsdon and Eifel suggest boosting residual lateral pelvic wall disease after 40 to 45 Gy whole pelvis to 60 to 62 Gy to small volumes (85). Perez et al. found a trend toward increased pelvic control with point B doses (defined at 6 cm lateral to the central axis) >45 Gy (116,262). In the 1973 and 1978 PCS, there was no relationship between lateral dose >60 Gy and either infield pelvic control or survival, but the lateral dose did impact complications with an increase above 50 Gy (118,120,121). There was a trend toward decreased failure with increasing parametrial doses in stage III disease (119). Perez et al. found that the incidence of pelvic recurrence was correlated with tumor size and dose of irradiation delivered to the lateral parametrium. There was an increase in the incidence of pelvic recurrence in patients receiving less than 50 Gy, but no correlation with increasing doses of irradiation (263). Doses needed to eradicate parametrial disease in the literature are typically around 60 Gy, combining the external beam doses with the implant doses. The proximity of small bowel can make this a risky proposition. Perez et al. noted that with doses below 50 Gy to the lateral pelvic wall, the risk of small bowel complications was about 1% and somewhat higher with larger doses (141). In a later series, grade 3 small bowel sequelae were 1% with doses of 50 Gy and 2% to 4% with doses over 60 Gy ($p = 0.04$) (264). At present, Perez et al. recommend limiting the small bowel doses to less than 60 Gy. Ferrigno et al. found an increase in small bowel complications when parametrial boosts were above 59 Gy. They recommended dropping the superior border of the parametrial fields to the S2–3 level and limiting the total dose to 54 Gy (194). The use of concurrent chemoradiation may allow a decrease in these doses, but data is too preliminary to conclude what this dose should be. When there is uterosacral space involvement, thought should be given to the use of a supplemental posterior oblique external beam boost (226). Grigsby et al. used PET/CT scans to evaluate lymph node size, irradiation dose, and patterns of failure. The parametrial and lymph node boost doses used were in the range of 9.0 to 14.4 Gy following large field doses of 50.4 Gy. Radiation dose and lymph node size were not significant predictors of lymph node failure. The risk of an isolated lymph node failure was <2% (265). A reoperation series following definitive irradiation and chemotherapy was reported by Houvenaegel et al. After 45 Gy and whole pelvis and selective parametrial or nodal boosting to 55 to 60 Gy, 15.9% of patients had biopsy-proven residual disease in the pelvic nodes and 11.7% of paraaortic nodes (266). Use of IMRT may be a method to increase dose

to bulky nodes or residual parametrial disease while sparing adjacent normal structures (35,47,46).

Endometrial Cancer

For endometrial cancer, many of the same nodes are at risk as in cervical cancer, but the spread of disease is not as predictable with the paraaortic nodes independently at risk. The presacral nodes are also not at risk unless there is cervical involvement. Both the pelvic and paraaortic nodes are at risk in all sites of uterine involvement, and grade, myometrial invasion, and lymphatic vascular space invasion are more predictive of risk than location (267–271). Cervical and lower uterine segment involvement also increases the likelihood of pelvic and paraaortic lymph node metastases compared to fundal location, as do increasing histologic grade and myometrial invasion. In the surgical staging series of Boronow et al., 18 of 222 patients had lower uterine segment involvement and 6 (33%) had pelvic lymph node metastases (270,272). In the final GOG surgical staging series report, by location, patients with fundal lesions had a 4% risk of paraaortic and 8% risk of pelvic lymph node involvement, whereas patients with lower uterine segment involvement had a 16% risk of pelvic and 14% risk of paraaortic lymph node involvement (274).

In endometrial cancer, external beam irradiation is generally recommended for patients thought to be at significant risk for lymph node metastases and/or a vaginal cuff recurrence. Traditionally, this has been recommended in the absence of a lymph node dissection or a limited lymph node sampling. External beam irradiation is also still delivered at many institutions in the setting of a negative lymph node dissection when high risk features such as deep myometrial invasion, high grade, lymphatic vascular space invasion, lower uterine segment involvement, or cervical invasion are present (273,274).

External beam irradiation typically covers the upper one-half to two-thirds of the vagina, the pelvic lymph node regions, and the surgical bed (Fig. 12.54). External beam field design must necessarily include the pelvic lymphatics with exclusion of as much small bowel as possible. Treatment of the patient in the prone position with a full bladder will help to exclude at least some small bowel in most patients unless these loops are fixed in the pelvis (Fig. 12.55). It is important, however, for the lateral fields to also cover the course of the external iliac nodes, which are quite anterior in the pelvis and require inclusion of some

FIGURE 12.54. Digitally reconstructed AP **A:** and lateral **B:** radiographs with nodal volumes contoured as well as the vaginal apex and the fields defined by the leaves of multileaf collimator. This is a standard field design for patients with endometrial cancer.

FIGURE 12.55. **A:** Utility of the prone technique for small bowel displacement as shown on a sagittal and axial CT scan of a patient with endometrial cancer planned in the prone position. **B:** Radiographs of the pelvis showing significant amount of small bowel in the radiation fields.

small bowel in the lateral fields to be adequately covered. Doses of 45 to 50.4 Gy are typical, with some institutions treating to 40 Gy and as high as 60 Gy to reduced fields in the setting of nodal disease. Whole pelvic fields are generally reduced or a midline block is added after variable doses.

Prone techniques have been used in the treatment of many other pelvic malignancies to attempt to exclude small bowel from the field. Use of a belly board device to further enhance small bowel displacement has become standard practice for many pelvic malignancies (275–277). Use of prone position with or without a belly board for the treatment of patients with cervical cancer has been reported in a few series, in the postoperative (275,276,278–280) and definitive settings (275–277,280,281). Prone positioning with the belly board has been used extensively for patients with rectal cancers when using a PA and two lateral fields. Concern over use of this technique for patients with gynecologic malignancies when adding a fourth field (AP) to cover the external iliac nodes has been raised by Ghosh et al. due to the uncertainty in source to skin distance (SSD) and variation in tissue thickness from the anterior field. In patients who underwent postoperative irradiation for cervical cancer, they observed that the small bowel was best excluded from the AP-PA fields when the patient was positioned prone without the belly board, thereby compressing the small bowel laterally out of the AP-PA fields. They recommended an alternating routine (278). Bladder distention can also help to optimally displace bowel when using the belly board (275,277). Concern over use of the belly board in patients treated with definitive versus postoperative irradiation for cervical cancer is also raised due to the potential change

in position of the uterus when prone, the impact and variability of bladder filling, and the potential daily variation in the setup (278,280,281). There is also some concern that, in patients with intact uteri, the prone position may increase the volume of the rectum treated (280). CT-based dosimetry has documented that the prone position, particularly with bladder filling, can alter the position of the uterus within the radiation field (234,236,281). Hence, if patients are simulated prone, it is even more imperative to use CT- or MRI-based dosimetry in the prone position to make sure that the entire uterus is in the pelvic fields, and it is also imperative to consistently fill or empty the bladder (281,282). IGRT may also be helpful in ensuring that the daily setup is reproducible and reliable.

Extended Field Irradiation

Extended field irradiation refers to inclusion of both the pelvic and paraaortic nodes in the radiation fields. Common indications for extended field irradiation in gynecologic cancers include patients with positive paraaortic nodes or those with positive pelvic nodes or bulky primary lesions feared to be at risk for microscopic paraaortic disease (Fig. 12.56). Extended fields include more normal organs than pelvic fields alone. Limitation of dose to the small bowel, kidneys, liver, stomach, and spinal cord are essential. Three-dimensional conformal techniques are helpful in achieving an acceptable therapeutic ratio. Use of IMRT has recently been piloted in this setting with further attempts to decrease acute and late toxicity (Fig. 12.20).

FIGURE 12.56. Axial CT scan demonstrating an enlarged periaortic lymph node near the left renal hilum.

Selective boosting of gross nodal disease may allow for safer dose escalation (45–47).

Pelvic and Inguinal Irradiation

External beam fields will necessarily include the inguinal lymph nodes in patients with vulvar cancer or distal vaginal cancers or when cancer of the cervix or endometrium involves the distal vagina. Risk of femoral head necrosis or femoral neck fractures is increased in this setting. Recent use of IMRT to treat vulvar and vaginal cancers has been published with success (50).

Whole-Abdominal Irradiation

Whole-abdominal irradiation is used to cover the entire abdominopelvic cavity in ovarian cancers or high-risk uterine cancers such as those with positive peritoneal washings or adnexal involvement (IIIA disease). This requires limiting the radiation dose to a maximum of 30 Gy to the entire abdomen and using lower fraction sizes of 150 to 170 cGy. This will reduce both acute and late toxicities. Careful attention to and limitation of the dose of radiation delivered to the liver and kidneys requires selective blocking of these structures at different doses (283,284). IMRT techniques are also being explored for whole-abdominal irradiation to reduce doses to the GI tract, liver, kidneys, and bone marrow and increase dose to the peritoneal surfaces and lymph nodes (48,49).

Radiation-Induced Tissue Effects

Side effects that develop during the course of radiation and persist for 3 months or less following completion of radiation are termed acute side effects. Those toxicities that develop later than 3 months after the completion of radiation are termed late or chronic effects. The late effects of radiation are due to damage at the capillary level where there is endothelial cell proliferation resulting in less diffusion of oxygen into the tissues with resulting fibrosis. There is less resistance to infection, trauma, or functional stress due to this change in vasculature and circulation (285,286). When treating gynecologic cancers, the normal tissues most often incidentally irradiated in the pelvis

are the rectosigmoid, small bowel, bladder, vagina, and pelvic bones and bone marrow. In the upper abdomen the kidneys, liver, stomach, small bowel, large bowel, and spinal cord may be in the radiation field. The response of a tissue or organ to radiation depends on two factors: (a) the inherent sensitivity of the individual cells, and (b) the kinetics of the population as a whole of which the cells are a part. These factors combine to account for the substantial variation in response to radiation characteristic of different tissues (1). Additionally, the volume of tissue irradiated as well as the dose, dose rate, and fractionation scheme will affect both acute and late toxicities. The addition of chemotherapy or other systemic agents may impact toxicity, as may other medical comorbidities such as diabetes, hypertension, collagen vascular diseases, Crohn's disease, and ulcerative colitis, as well as social risk factors such as smoking. The most comprehensive data describing the effects of radiation on the normal tissues was published by Rubin and Casarett and later updated by Emani et al. (286,287). Rubin and Casarett defined tolerance doses (TD) for almost all of the tissues. The TD 5/5 is defined as the probability of a 5% risk of complications within 5 years of the completion of radiation, and TD 5/50 as the probability of a 50% risk of complications within 5 years (286). More recently, the QUANTEC (Quantitative Analyses of Normal Tissue Effects in the Clinic) guidelines have been published with updated recommendations (288,289).

Skin

When treating abdominopelvic tumors with radiation, often there will be minimal skin reactions due to the skin-sparing quality of the high-energy radiation beams used to treat these sites deep within the body. Contrastingly, when treating the vulvar and inguinal regions, where electrons or lower energy X-rays are more often used, there can be marked skin reactions. Skin reactions are also more likely to develop in skin folds such as the inguinal creases or intergluteal fold. The cells in the basal layer of the skin are very sensitive to radiation, but because of the time required for these differentiating cells to move from the basal layer to the keratinized layer of skin, there is a 2- to 3-week delay between the start of radiation and the appearance of skin reactions. Erythema is the first visible skin reaction due to dilation of the small capillaries and is usually seen about the third week of radiation. Other skin reactions include dry desquamation and moist desquamation occurring after the 4th week of radiation. Moist desquamation occurs with transient loss of the epidermis and exposure of the dermis. Serous fluid often oozes from the exposed and inflamed dermis (286,290). These effects may be enhanced by the combination of irradiation and some chemotherapeutic agents, particularly actinomycin D and doxorubicin (Adriamycin) (293). It is also well known that chemotherapy agents such as Adriamycin or gemcitabine can “recall” radiation reactions after the original reaction has subsided (291,292). Radiation-induced skin reactions are treated with various topical ointments and creams as well as with sitz baths and special emphasis on cleansing all stool and urine gently from the perineum. Additionally, if the distal vagina or vulva is in the radiation field, patients may also complain of dysuria or painful defecation, which is due to the caustic effects of the urine and stool on the denuded epithelium of the distal vagina, perianal area, and vulva. Diarrhea control and use of barrier creams to protect the irritated skin from stool and urine will help to minimize discomfort and hasten skin healing. Sulfa-based creams and Domeboro soaks can be used to expedite healing. Return of the epidermis can take 10 to 14 days. Residual surviving basal cells form islands of regeneration, which proliferate to re-epithelize the area. Islands of skin forming in the desquamated skin herald skin renewal. The new skin is thin and pink with gradual return to normal

in 2 to 3 weeks (286). Late manifestations of radiation on the skin include depigmentation, subcutaneous fibrosis, dryness and thinning with loss of apocrine and sebaceous glands, thinning or loss of hair, and telangiectases. Necrosis of the skin is rare and generally occurs only with very high doses of radiation in excess of 60 Gy (286,293).

Bone Marrow/Pelvic Bones

The lymphocytes are the most radiosensitive cells in the bone marrow. The rate of fall of the various components of the marrow is a function of the half-lives of the mature cells. These half-lives are as follows: erythrocytes, 120 days; granulocytes, 6.6 hours; and platelets, 8 to 10 days (286). Pelvic irradiation may cause transient lymphopenia. This is even more of an issue when whole-abdominal or extended-field irradiation is used due to the increased bone marrow in the radiation fields. This decrease in lymphocytes is thought to be the result of irradiation of the lymphocytes circulating through the vascular bed and may not be indicative of bone marrow reserve depletion. Prior or concurrent chemotherapy will also lead to increased bone marrow toxicity. Frequent monitoring of the CBC is considered standard of care with pelvic or abdominal irradiation. Permanent chronic changes are noted even when small segments of the bone marrow are irradiated to doses over 30 Gy, and recovery may take up to 18 months or longer in a proportion of patients with good reparative capacity.

Insufficiency fractures can also develop in irradiated pelvic bones (293,294,295). These most commonly involve the sacrum and ileum, followed by the pubic bones, and rarely the acetabulum. Patients may complain of sudden onset of back or groin pain, which worsens with weight bearing and changes in position. MRI is the best imaging modality to detect them and also rule out recurrent disease. Sometimes edema will be reported in the absence of actual fractures, and in other cases, actual fractures will be seen. It is important not to confuse these changes with metastatic disease, as further palliative irradiation would worsen the integrity of the bone. Symptoms from these changes in the pelvic bones will often improve over time, but patients may also suffer future symptoms from exacerbation of these fractures or development of new fractures over time. Sacroplasty can be used if patients remain symptomatic. Narcotics and changes in activity are often required. Femoral neck complications can include avascular necrosis as well as fracture. This is a rare complication following irradiation of the inguinal nodes. Hip replacement surgery is required to resolve this problem (296).

Liver

During whole-abdominal irradiation or paraaortic irradiation, the liver is in the radiation field and dose must be limited to this critical organ. Clinical and pathologic studies have shown that the liver is not a radioresistant organ. Venooclusive disease is the pathologic entity caused by radiation. Necrosis and atrophy of the hepatic cells result from this change in blood supply. CT scanning following radiation can show changes in perfusion of the liver corresponding to the radiation fields. These changes are not always associated with toxicity. The clinical course and liver changes depend on the dose-fractionation scheme and volume of irradiation as well as the presence of chemotherapy and preexisting liver disease. During radiation, the liver enzymes may be elevated. This can continue following completion of radiation. Signs of radiation hepatitis can include a marked elevation of alkaline phosphatase (3 to 10 times normal), with much less elevation of the transaminases (normal to 2 times normal) (286,297). Liver enlargement and varying amount of ascites can also evolve. If the doses and volumes are high enough, liver failure can occur.

The TD 5/5 for whole liver is 30 Gy in 2 Gy fractions (286,287). Small portions of the liver can receive up to 70 to 90 Gy. Mean liver doses of <28 to 32 Gy at 2 Gy per fraction are recommended (298).

Kidney

The kidneys are very sensitive to small doses of radiation, and a common goal is to avoid greater than 18 to 20 Gy whole kidney dose. When delivering whole-abdominal irradiation, the kidneys are at risk and must be blocked at acceptable doses to prevent renal failure. When delivering paraaortic irradiation, the kidneys are also at risk and treatment planning CT scans can help to define which beam angles are best to irradiate the nodal regions yet miss, in part, the kidneys. When planning radiation fields, sometimes one kidney will need to be irradiated more than the other and the equivalent of one kidney must be spared. Chemotherapy can lower kidney tolerance to radiation as can increasing age. Irradiation of only one kidney does not necessarily reduce the risk of renal complications (299). Functional renal studies prior to radiation are important in documenting unexpected perfusion or excretion abnormalities and in determining how much each kidney contributes to total renal function. Functional changes have been described after exposure of the kidney to more than 20 Gy, and signs and symptoms of renal dysfunction can follow including hypertension, leg edema, and a urinalysis showing albuminuria and low specific gravity (299). A normocytic, normochromic anemia may also appear. Renal function studies will ultimately show decreased blood flow and filtration rates. CT scans may reveal a small kidney if one kidney has been preferentially irradiated to protect the other (286). Current dose-volume recommendations are found in the QUANTEC data (299).

Ovaries

In premenopausal patients treated with definitive irradiation, the ovaries will be irradiated incidentally and ovarian failure will occur. Hot flashes and other menopausal symptoms can begin to develop during radiation. Hormone replacement therapy is an important consideration in women younger than 50. Alternatively, midline oophorectomy has been used in young women requiring irradiation for Hodgkin's disease in an effort to spare the ovaries. The ovaries can also be elevated out of the radiation field and placed above the true pelvis to attempt to avoid them when treating cervical cancer. The radiosensitivity of the ovarian cells varies considerably with age. The dose necessary to castrate a woman depends on her age. A larger dose is required during the period of more active follicular proliferation. A single dose of 4.0 to 8.0 Gy or fractionated doses of 12 to 20 Gy (depending on age) are known to produce permanent castration and sterility in most patients (285,286,293).

Vagina

There are few noticeable acute reactions when treating the upper two-thirds of the vagina with radiation. Some patients may notice a white-yellow vaginal discharge, which is due to mucositis of the vaginal mucosa. This can be evident during radiation and can continue for several months after radiation (286). The lower third of the vagina, however, will become quite irritated when irradiated, in part due to irradiation of the vulva and urethra as described above. The distal vagina is less tolerant of radiation than the proximal, and the tolerance doses are in the range of 80 to 90 Gy versus 120 to 150 Gy, respectively (300). There are, however, no studies that have successfully correlated

DVH parameters with morbidity (301). Vaginal narrowing and shortening is a late sequela of radiation, which can alter and impede sexual function. Combined brachytherapy and external beam irradiation will cause more late effects than either modality alone. Use of a vaginal dilator or intercourse 2 to 3 times/week can help to keep the vagina open. Use of lubrication with intercourse as well as estrogen creams to build up the vaginal mucosa can also make intercourse more comfortable (293,302). Rarely, with excessive doses of radiation, patients can develop vaginal necrosis. This is due to a change in blood supply to the vaginal tissues and is much more common at the introitus than at the vaginal apex, perhaps due to the vascular supply of the vagina. The posterior vaginal wall is most frequently involved (300). Interstitial implants are more likely to cause necrosis than intracavitary implants. Hydrogen peroxide douches, antibiotics, and hyperbaric oxygen therapy can help the vaginal tissues to heal (303,304). Narcotics are often necessary to control the associated pain until healing has occurred. Trental (pentoxifylline) can also help soft-tissue necrosis to heal (305). The uterus is very resistant to high doses of radiation as is evident in patients treated with external beam and brachytherapy for cervical cancer. Rare cervical necrosis can occur and will respond readily to hyperbaric oxygen treatments and pentoxifylline (286,304,293). There may be an increased risk of this in patients using cocaine. Necrosis can also be caused by recurrent tumor, and distinguishing recurrent disease from necrosis can be very difficult and sometimes will mandate surgical intervention (286).

Stomach, Small and Large Intestine

The stomach is lined with a mucous membrane, which is columnar epithelium and sensitive to radiation. Like the small and large bowel reactions, the stomach lining develops erosions and thinning and subsequent edema and ulceration. Symptoms can include nausea, vomiting, reflux, and pain. Use of prophylactic antiemetics and proton pump inhibitors can decrease the acute effects of radiation. Acid production can be decreased during radiation and for up to 1 to 2 years after. Late effects can include gastritis and ulceration with associated bleeding. Progressive fibrosis can lead to gastric outlet obstruction and rarely perforation, all of which are dose and volume dependent (286). The entire stomach can tolerate doses of 45 to 50 Gy, but data on maximum tolerated doses are inadequate (306).

The acute effects of radiation on the small intestine are due to the inherent radiation sensitivity of the rapidly dividing undifferentiated crypt of Lieberkuhn cells. The normal lining of the GI tract is a self-renewing tissue. These undifferentiated stem cells normally migrate and differentiate upward from the lower half of the crypts to the tips of the intestinal villi as they mature, providing a continuous supply of surface cells as they divide. Their function is to primarily form absorptive cells but also mucous-secreting goblet cells and endocrine cells (285,286,290). The mature cells at the surface of the villi are repeatedly sloughed and replaced by the cells, which originate in the crypts. These undifferentiated crypt cells are the most sensitive to radiation and are preferentially depleted, leading to loss of mature replacement cells at the surface of the villi. When these mature mucosal cells cannot be replaced, the villi shorten and the loss of absorptive function of the small intestine occurs. This loss of function results in fluid and nutrient wasting, diarrhea, and dehydration. This constellation of symptoms is termed acute radiation enteritis. Fortunately, re-epithelialization occurs within several days due to recovery of the rapidly dividing crypt cells (290). Mucosal healing will occur within 10 to 14 days if radiation is terminated, and symptoms will accordingly improve and resolve in most patients. It is common to observe watery diarrhea with intermittent abdominal cramping starting in the second or third week of abdominal or pelvic irradiation.

Increased peristalsis, disturbance of the absorption mechanisms, and a decreased transit time also occur. Patients will report increased flatulence and noisy bowel sounds. Rarely patients will report nausea. Implementation of a low residue diet, hydration, and use of antimotility agents can be very helpful. Some patients may be lactose and fat intolerant as well. Judicious use of narcotics to calm the bowel can also be helpful. Concurrent 5-FU or gemcitabine can worsen small bowel toxicity with diarrhea from the 5-FU often appearing before the radiation enteritis has had time to evolve. The late effects of radiation on the small bowel can be a continuation of the acute effects. Some patients will experience chronic diarrhea that will require a permanent change in diet. Certain foods may trigger diarrhea such as those high in fiber or fat. Spicy foods and MSG may also trigger diarrhea. Areas of narrowing corresponding to regions of high dose or adhesions can occur in the small bowel loops and lead to partial obstruction of the small bowel. Patients may report abdominal pain and distention followed by diarrhea and relief of these symptoms. A complete bowel obstruction would also be characterized by abdominal pain and distention in addition to vomiting and lack of bowel movements. Small bowel obstructions occur in approximately 5% of irradiated patients and surgical intervention is required in some to relieve these obstructions. Prior surgeries or a history of a perforated appendix or pelvic abscess as well as inflammatory bowel disease can increase the risk of small bowel toxicity as can the use of chemotherapy. Hypertension and diabetes can also be risk factors as can thin body habitus. Radiation to large volumes of bowel or high doses to even small volumes of bowel can lead to bowel obstructions. The ileum is the most common loop of bowel involved (286). Malabsorption of fats, carbohydrates, protein, B₁₂, and lactose can occur in some patients. Excessive bile salts can reach the colon and act as a cathartic, and medications such as cholestyramine can be helpful in controlling the resultant loose stools.

Small bowel doses should be limited to 45 to 50 Gy with 60 Gy maximum (264). Current recommendations for small bowel dose/volume constraints are as follows: The absolute volume of small bowel receiving >15 Gy should be <120 cc when delineating individual loops of bowel. If the entire peritoneal space is defined, the volume of small bowel receiving >45 Gy should be <195 cc (306).

The rectosigmoid mucosa is also a rapid renewal system similar to the small bowel. When the rectum is included in the irradiated volume, there is rectal discomfort with tenesmus and mucous production, sometimes mixed with blood in the stools. Patients may report frequent and sometimes painful evacuations of only small amounts of stool mixed with mucus. Hemorrhoids may worsen during radiation. This constellation of symptoms is termed "proctitis." Medications to decrease the number of stools as well as antispasmodic agents can be helpful. Suppositories or foams with steroids can be helpful, as can topical perianal skin ointments and lotions. Uncontrolled radiation enteritis can worsen radiation proctitis due to frequent stooling through the irritated rectum. For late effects, if the dose of radiation is large enough, it may cause temporary or permanent ulceration and bleeding due to telangiectasias (Fig. 12.57). Cortisone-containing rectal suppositories and foams or sulfasalazine instillations can also help to heal the bleeding and ulcerated rectal mucosa as can argon laser ablation of the telangiectasias.

Hyperbaric oxygen therapy can be helpful in controlling bleeding when severe (304,307,308,309). Fibrosis, stenosis, perforation, and fistula formation are rarer (Fig. 12.58). In general, doses in excess of 60 Gy are necessary to produce this more advanced radiation damage to the small bowel and rectosigmoid (310). Fecal diversion may be necessary in the setting of stenosis, necrosis, or fistula formation. Retrospective analyses have shown that limited volumes of the rectum can tolerate about 75 Gy (external beam and brachytherapy) with acceptable morbidity (257,264).

FIGURE 12.57. Radiation-induced telangiectasias of the rectum consistent with radiation proctitis.

Bladder/Ureters/Urethra

The bladder and ureters have a rapidly renewing transitional epithelium. The effect of radiation is early denudation similar to the skin due to injury to the rapidly dividing basal cells. Epithelial desquamation leads to focal ulcerations, hyperemia, and edema of the bladder wall, which is visible at cystoscopy (286,290,311). Acute and transient radiation cystitis may be observed with moderate doses of irradiation (>30 Gy) and usually requires no specific treatment. Patients will report urinary frequency and urgency as well as mild dysuria, as well as decreased bladder capacity. However, with higher radiation

doses, more severe symptoms of cystitis develop, such as severe dysuria and hematuria, which may require treatment. Agents such as Pyridium may help lessen these symptoms. Significant spasms of the bladder musculature, which may be improved with administration of smooth muscle relaxants, may also occur. It is important to rule out the presence of a concomitant bacterial infection, which may exacerbate the symptoms. Infections are seen at an increased rate in irradiated patients, perhaps in part due to radiation-induced diarrhea and contamination of the perineum. Urinalysis and urine cultures obtained under sterile conditions, when indicated, should be obtained before institution of antibiotic therapy. Radiation cystitis is characterized by the presence of white cells and red cells without bacteria on urinalysis.

With doses above 60 Gy, chronic cystitis and hematuria may be observed due to telangiectasias, which can develop in the bladder lining (85,312). With higher doses, more severe chronic cystitis, fibrosis, and decreased bladder capacity can occur. Rarely, bladder neck contractures as well as fistulas may occur, which can necessitate surgical intervention. Fistulas are more likely to occur if there is invasion of the bladder wall by tumor or in the setting of interstitial implants. Surgery may be required to deal with some of these complications (286). Hyperbaric oxygen therapy can be very helpful with hemorrhagic cystitis, as can the drug pentosan polysulfate (Elmiron), which has been used for interstitial cystitis (304,307,313). The ureters are quite resistant to radiation and rare ureteral stenosis is reported in some series (257,286,311,314). This can require stenting or rarely diversion. Interstitial implants are more likely to cause this than intracavitary implants, as can early placement of a narrow midline block (257). Urethral stenosis is also rare and is also more likely to occur with interstitial than intracavitary approaches. Careful dilation can be helpful in sustaining bladder outflow (311).

Bladder and Rectosigmoid—LDR

The bladder and rectosigmoid are the organs of concern in the setting of combined external beam irradiation and brachytherapy. Dose and volume are considered two important variables related to complications. Dose has been thought to be an

FIGURE 12.58. Radiation-induced sigmoid stricture noted on a contrast study. **A:** full view, **B:** magnified view, following definitive chemoradiation.

important determinant of normal tissue complications. Attempts have been made to determine the maximum tolerable normal tissue dose with an acceptable risk of complications. There is no consensus as to what these values should be. Point doses may or may not coincide with complication risk, as they do not account for the volume of organ irradiated. They are also not defined consistently. Maximum bladder point doses of 75 to 80 Gy and rectal doses of 70 to 75 Gy are guidelines (82,264,312,310). The ratio of dose to the rectal point and bladder point and dose to point A is also important with a low incidence of rectal (0.3% vs. 5%) and bladder (2% vs. 2% to 5%) complications when this ratio was less than 80% (264). Other factors such as external beam dose and intracavitary dose rate are also important in the etiology of complications. The volume of rectum and bladder irradiated is an important variable in the development of complications in addition to the cumulative dose (315). Both external beam and use of tandem and cylinder applicators can increase the volume of bladder and rectum treated (130,316). Stage, patient age, and medical comorbidities such as hypertension, diabetes, diverticulitis, or inflammatory bowel disease may also increase the risk of complications, as can the administration of chemotherapy. Individual radiosensitivity may also impact complication risk (317).

Bladder and Rectosigmoid—HDR

Acceptable normal tissue doses are even more debatable in HDR than LDR. Using HDR techniques, the therapeutic range is narrower and the risk of complications seems to rise faster than the rate of improved tumor control. Available clinical data also suggests that in addition to total HDR dose, the most important factor in late complication development is the dose per fraction and the number of fractions (162,317,318). The organ most at risk for complications is the rectosigmoid, whereas the bladder complication risk is comparatively low (188,319,320). Rectal and sigmoid complications occur earlier than bladder complications (317,318). Rectal bleeding is the most frequent rectal morbidity occurring in approximately 30% of patients (257,319,320,321). To avoid excessive morbidity, better physical dose distributions must be achieved with HDR to reduce doses to critical normal structures. This implies the use of rectal and bladder displacement. Fowler has speculated that if only 80% of the tumor dose is received by the critical normal tissues, then 4 to 6 HDR fractions can be used safely, whereas 12 to 16 fractions would be required if the normal structures receive 90% of the point A dose, and 30 fractions if the normal structures received 100% of the HDR dose (162,322). Rectal retractors have become an integral component of insertion techniques and perhaps improve the effectiveness and reproducibility of rectal displacement over gauze vaginal packing (162,161,163). Whatever the case, a rectal retractor, vaginal speculum blade, or gauze packing should be used to displace the rectum (170,189).

Various disparate recommendations concerning normal tissue fraction size and total dose exist in the literature. Sakata et al. found that the probability of rectal complications increased dramatically above a maximal rectal dose (D_{eq}) of 60 Gy (323). Cheng et al. found that patients with >62 Gy of summed external beam and intracavitary doses to the proximal rectum and >110 Gy maximal proximal rectal BED had significant increase in complications (324). Takeshi et al. noted that radiation dose significantly impacted rectal dose complication rate with an increase above 65 Gy (325). Various recommendations for rectal and bladder tolerance doses are in the literature using point doses and time–dose fractionation (TDF) and biologically equivalent dose (BED) values (194,257,259, 320,326–332). When using point doses, it is very important to choose points related to critical structures very carefully on the orthogonal films. Rectum above the level of the vaginal applicators and rectal retractor

should be identified and sigmoid in addition to rectal points should be evaluated, as should bladder and vaginal points. Various methods for determining normal tissue doses have been described. When possible, the doses to the normal critical structures should be less than the dose at point A, perhaps in the range of 50% to 80%. The portions of the rectum and sigmoid that are above the range of the rectal retractor are most often the hot spots, and every effort must be made to decrease the dose to the rectosigmoid relative to the point A dose. Consideration to decreasing the dwell times or turning off dwell positions in the tandem should be given. To avoid underdosing endometrial extension of tumor, at least treating 4 cm above the exocervix so that point A is not in a region of dose constriction may be wise. Tandem lengths of 6 to 8 cm are typical. If there is endometrial extension, a longer tandem may be needed. Additionally, use of a tapered tandem will decrease sigmoid, bladder, and small bowel doses (175). Contrast in the sigmoid is helpful in making these decisions. CT scanning after applicator placement is exceedingly helpful and much more reliable in assessing the proximity of the sigmoid to the tandem and in manipulating the dose distribution (Fig. 12.59). Assessment of the anterior and posterior uterine wall thickness measured on CT with the applicator in place, along the course of the tandem, as well as the measured distances from the tandem to the rectosigmoid, small bowel, and bladder, can help to guide dose prescription and potentially decrease toxicity if the distribution is altered appropriately (105). Sigmoid doses can often be higher than the rectal ICRU doses (324). Van Lancker and Storme have not found point A or normal tissue dose points helpful as predictors of complications, but rather that volume calculations were extremely helpful in predicting complications, and they found a significant correlation between rectal complications and the ICRU reference 60 Gy isodose volumes (333). Dose volume data appears to be more helpful than point dose data in predicting for complications. Using CT or MR based volume planning, the EQD2 limit to the D2cc (the minimum dose in the most irradiated 2 cm³ normal tissue volume for the rectum and sigmoid is 70–75 Gy and for the bladder, 90 Gy (112,113,115,107). Georg et al. found that for the rectum, a significant dose effect was found for all DVH parameters for any grade of complication as well as for G2 to G4 side effects with the exception of the D0.1cc. For G2 to G4 rectal toxicity, a threshold of 60 Gy (EQD2) was observed with a 10% incidence at 78 Gy and a 20% incidence at 90 Gy. For bladder, no significant dose response was observed for G1 to G4 side effects, but for complications of >G2, dose effect curves could be generated for all DVH parameters that were statistically significant. For bladder, there was a 5% risk of G2 to G4 morbidity with a D2cc of 70 Gy, a 10% risk of G2 to G4 morbidity with a D2cc of 101 Gy, and a 20% risk of G2 to G4 morbidity with a D2cc of 134 Gy (334,335). Late bladder sequelae have been infrequent in patients with such doses but longer follow-up is needed to be certain as the late effects in the bladder can be quite delayed in their appearance (115). Georg et al. and Kook et al. also found a correlation between rectal dose volume parameters and endoscopically defined mucosal changes as well as clinical side effects (337,336).

FUTURE FOCUS

Reduction of morbidity and improvement in local control and cure is a common goal in the treatment of patients with gynecologic cancers. Use of 3-D and functional imaging will be increasingly important to define tumor and normal tissues. This can perhaps allow escalation of dose to the tumor and reduction of dose to the critical normal tissues. There has been, however, a reluctance to vary from traditional dose specification as good outcomes have been published at institutions skilled in the care of gynecologic

FIGURE 12.59. Radiograph of the pelvis with a tandem and ovoid applicator in place demonstrates the circuitous course of the sigmoid **A**. The axial CT scan **B** demonstrates a more accurate relationship of the sigmoid to the uterine tandem and the need to limit dose to this loop of sigmoid positioned very close to the high-dose region of the implant.

patients. It is potentially dangerous to optimize therapy to such an extent that the dose distribution looks dramatically different from the traditional “pear shape,” which effectively encompasses the primary tumor and parametria in cervical cancer presentations. Making this pear too narrow to avoid critical structures may lead to a higher rate of local recurrence. Yet it is important to treat the disease and not just strive for an ideal dose distribution. Preliminary studies using CT indicate that we underestimate normal tissue doses with the present 2-D dosimetric analysis used at most institutions (103,317,106). Whether this information should change the way we prescribe doses remains debatable. Directly relating the intracavitary system to the anatomy through use of CT and MRI seems to be the next step in the lineage of dosimetric systems (Fig. 12.60) (103,104,106). The GEC ESTRO GYN Working Group has developed guidelines for defining and contouring tumor volumes and normal tissues on MRI scans with the brachytherapy applicators in place (112,113). These guidelines are now incorporated into the EMBRACE study, which is actively accruing patients in a large registry to study the impact of image-based brachytherapy on tumor control and normal tissue toxicity. The excellent soft-tissue resolution of MRI allows visualization of residual tumor in relation to the isodose distribution around the MRI compatible brachytherapy applicators (Figs. 12.33 and 12.60) (108,111). Data from Potter et al. have shown a decrease in complications and an increase in local control with the use of MRI-guided brachytherapy for cervical cancer (114,115). Additionally, the use of dose-volume histogram analysis may add new insight into optimizing local control and decreasing morbidity with a better understanding of the importance of dose-volume relationships. This may be a powerful tool to help improve the therapeutic ratio in patients with gynecologic cancer and will best be achieved through collaboration of radiation oncologists, gynecologic oncologists, and diagnostic radiologists.

MICHAEL A. BOOKMAN

HISTORICAL OVERVIEW OF CANCER CHEMOTHERAPY

We are in the midst of an important transition from conventional cytotoxic agents to new strategies that incorporate molecular-targeted therapeutics. Even with these changes in our treatment paradigm, several conventional cytotoxic agents maintain a central role in the care of women with gynecologic cancers. In that context, a brief review of drug development provides a framework to understand the evolving balance between toxicity, efficacy, and design of treatment regimens.

The first report of a drug-mediated tumor response was noted over 125 years ago using Fowler's solution (arsenic trioxide in potassium bicarbonate) in patients with Hodgkin's disease and leukemia (1). Arsenic compounds had been used for various medicinal purposes for over 2,000 years, and it was not surprising that they were tested in patients with cancer. Cyclic hematologic toxicity was observed following arsenic administration in normal individuals and patients with leukemia (2), establishing a close association between tumor response and host toxicity that still exists today. Cumulative dose-limiting toxicity (arsenic poisoning) was also described following expanded utilization of arsenic in chronic myelogenous leukemia (3), coinciding with a transition toward radiation therapy for the management of leukemia and lymphoma around 1940.

The term *chemotherapy* has been attributed to Paul Ehrlich, a Nobel laureate physician and bacteriologist, who developed *in vivo* rodent models of infection, including the introduction in 1910 of Salvarsan, an organic arsenical originally used to cure syphilis and still used in the management of trypanosomiasis. His early *in vivo* modeling also encouraged the development of inbred transplantable rodent tumors, thereby establishing a paradigm that has been widely adopted for screening new antitumor agents.

Although the topical vesicant properties of sulfur mustard received much attention during World War I, multiple systemic effects, including leukopenia, bone marrow aplasia, and mucosal ulceration, emerged with further study and would ultimately have greater importance. Cancer chemotherapy, in the traditional sense, began with the demonstration that nitrogen mustard had reproducible activity against transplanted lymphoma in mice, prompting clinical trials as early as 1942 (4). However, owing to World War II, much of the research remained classified until 1946. Following the demonstration by Farber in 1948 that aminopterin, an antifolate, could induce temporary remission in childhood leukemia (5), antimetabolites became the next major category of agents to be developed, and were ultimately associated with cures in women with choriocarcinoma (6). Research during the 1940s also included the Nobel Prize-winning observations of Huggins and others (7) regarding the antitumor effect of estrogens in prostatic cancer.

Conventional Cytotoxic Agents

Between 1945 and 1965, many important chemotherapeutic agents, such as actinomycin D, cyclophosphamide, 5-fluorouracil, Vinca alkaloids, and progestogens, were developed and demonstrated to have antitumor activity in clinical trials. Between 1965 and 1975, the pace of new drug discovery and development continued. During this period, cisplatin was shown to have activity in testicular and ovarian tumors, and doxorubicin, bleomycin, etoposide, and tamoxifen entered our clinical arsenal. This was followed by the identification of analogs, such as carboplatin, idarubicin, and vinorelbine, with antitumor activity similar to the parent compound but with a reduction in nonhematologic toxicity. The 1990s and beyond have brought important new agents into clinical practice, including the taxanes (paclitaxel and docetaxel), nontaxane microtubule-binding agents (epothilones), camptothecins (topotecan and irinotecan), nucleoside analogs (gemcitabine and capecitabine), alternative organoplatinums (oxaliplatin, satraplatin), an inhibitor of the proteasome complex (bortezomib), and an agent that binds to the minor groove of DNA, distinct from alkylating agents (trabectedin).

Attention has also been directed at alternative formulations of standard agents, including liposomal or polymer-based encapsulation, protein conjugation, nanoparticles, or lipid solubilization, to modify drug disposition, tumor targeting, and the potential for host toxicity. In addition, conventional agents have been utilized for regional (intraperitoneal) administration, prolonged intravenous infusion, continuous oral administration, high-dose therapy with hematopoietic progenitor cell support, and weekly low-dose therapy, each with the goal of improving the therapeutic ratio, but with a variable impact on host toxicity and clinical outcomes.

With the availability of multiple agents, each with a different molecular target, mechanism of action, pattern of resistance, and spectrum of host toxicity, we have also seen frequent utilization of multidrug combinations, particularly as primary therapy for advanced disease. The use of adjuvant therapy, including concurrent chemoradiation for early-stage disease, has been greatly expanded in selected clinical situations, with the result that a larger proportion of patients are exposed to chemotherapy at an earlier point in the natural history of their disease. Based on a combination of intrinsic and acquired factors, the majority of advanced tumors eventually demonstrate broad resistance to conventional cytotoxic chemotherapy, and there has been renewed interest in novel biologic and immunologic approaches with non-cross-resistant mechanisms. In addition, with improved understanding of the mechanisms associated with drug resistance, newer agents have been developed that may partially reverse resistant phenotypes through blockade of specific pathways, inhibition of DNA repair, or promotion of cellular apoptosis.

Molecular-Targeted Agents

Exploration of the biologic mechanisms associated with tumor invasion, metastasis, and angiogenesis has led to the development of inhibitors directed against metalloproteinases, adhesion molecules, and growth factors (including ligands and receptors). As basic research in tumor biology uncovers specific molecular targets, small molecules have been developed that modulate key pathways associated with tumorigenesis. These include blockade of gene products associated with specific activating (driver) mutations or genetic translocations, alterations in epigenetic factors (such as promoter methylation or histone modification), inhibition of protein tyrosine kinases associated with specific growth-factor receptors and downstream components of signal transduction, blockade of cyclin-dependent kinases and components of the mitotic apparatus associated with cell cycle progression, interference with posttranslational protein modifications (including proteasome function and catabolism), and modification of the host immune response.

In general, these novel targeted agents exhibit toxicities that are distinct from conventional cytotoxic chemotherapy, often sparing proliferative compartments, such as bone marrow and mucosal epithelium. However, there is still the potential for serious toxicity, including drug interactions, alterations in hepatic or renal function, bleeding, thrombosis, pneumonitis, leukoencephalitis, and autoimmunity.

A Contemporary Challenge: Drug Shortages

Trends in drug development within the academic community and pharmaceutical industry have dramatically changed over the last 10 years, and we are now seeing an abundance of new molecular-targeted agents, with only a limited investment in conventional cytotoxics. Many of our most widely utilized standard chemotherapeutic agents have exceeded the period of patent protection and are now produced and distributed as generic compounds. With reductions in insurance reimbursement rates and the rising expense associated with manufacturing and quality control, the profitability of generic medications and the number of generic manufacturing facilities have declined. This has contributed to intermittent and chronic shortages of a number of compounds, including cisplatin, paclitaxel, 5-fluorouracil, leucovorin, bleomycin, polyethylene-glycosylated liposomal doxorubicin, antiemetics, and steroids. Consequences include greater costs to obtain drugs through alternate sources, omission of specific drugs from standard treatment regimens, and closure or delay of important clinical trials. Solutions to this international problem are complex, and it is likely that important shortages will manifest for a number of years to come. Information on current drug shortages can be obtained from the U.S. Food and Drug Administration (FDA) and the American Society of Health-System Pharmacists (ASHSP):

TUMOR BIOLOGY IN RELATION TO CHEMOTHERAPY

Tumor Growth and Cellular Kinetics

Many of the principles of modern chemotherapy are derived from knowledge of the growth characteristics of normal and tumor tissues. Each tissue has an innate capacity for growth that is regulated by internal and external factors. The growth

characteristics of tumors differ from normal tissues, and the exploitation of these differences has provided the historical basis for utilization of radiation and chemotherapy. The cellular kinetics of normal tissues also explains many of the toxicities associated with chemotherapy. All normal tissues, particularly during fetal development and variably during adult life, possess the capacity for cellular division and growth.

The *static* population includes well-differentiated cells that arise from pluripotent fetal stem cells and rarely undergo cell division during adult life. Typical of this group are striated muscle, neurons, and nephrons, with oocytes representing a specialized subcategory. Damage to these cells can have long-term consequences and has prompted interest in stem cell biology.

The *expanding* population of normal tissues retains the capacity to grow, but in their adult state, they are normally quiescent. Under stress, especially after injury, a proliferative burst is followed by return to quiescence. Typical of this pattern of growth are the components of liver parenchymal tissue, including hepatocytes, bile duct epithelium, and vascular endothelium.

The *renewing* cell population is in a continuous proliferative state with ongoing cell division balanced by cell loss and terminal differentiation. Typical renewing populations include the bone marrow, epidermis, gastrointestinal epithelium, and spermatocytes.

The patterns of normal cell growth partially explain some of the toxic effects of cytotoxic therapy and why some tissues are commonly spared (8,9). Renewing cell populations with constant turnover are most sensitive to acute injury from conventional chemotherapy or irradiation. This is reflected by the frequent occurrence of dose-limiting bone marrow suppression, mucositis, and azoospermia during cytotoxic drug treatment, with relative sparing of nonproliferative compartments, such as brain, muscle, kidney, bone, and oocytes. However, even nondividing tissues can experience late chronic effects related to DNA damage.

Dysregulated growth of cancer cells occurs because of altered growth-factor signaling and/or disruption of checkpoint mechanisms that exist in normal cells. Despite a capacity for continuous growth, the actual process of cancer cell division is not more rapid than division in normal cells.

Programmed cell death, or apoptosis, has emerged as a major mechanism for regulating growth and development of tissues. Furthermore, certain oncogenes, like *c-myc* and *bcl-2*, and tumor-suppressor genes (antioncogenes), including *Rb* and *TP53*, are central to the regulation of apoptosis. Expression of these genes can alter the sensitivity of cancer cells to treatment with chemotherapy and radiation. For instance, overexpression of functional *bcl-2* and nonfunctional *p53* genes can render tumor cells resistant to a number of chemotherapeutic agents (10), suggesting that efforts to restore apoptotic signaling may improve chemosensitivity.

Emerging data have also described stem-like behavior in subpopulations of ovarian cancer cells, including dormant cells with a low mitotic index that exclude cytotoxic drugs from their cytoplasm and demonstrate increased resistance to chemotherapy (11,12). These stem-like cells are generally enriched during the repopulation that occurs following primary chemotherapy, and targeting of these distinct cell populations has become an important area of research.

Gompertzian Tumor Growth

During initial cell divisions, tumor growth seems to follow an exponential pattern. As the tumor grows larger, the rate of growth slows. This pattern of exponential growth with exponential growth retardation is known as gompertzian growth (Fig. 13.1). As the tumor mass increases, the time required to double the tumor volume also increases. The kinetic explanation for this apparent paradox is illustrated in Figure 13.2, which compares the number of cells in the tumor mass with the number of doublings (13). In accordance with gompertzian kinetics,

FIGURE 13.1. Hypothetical gompertzian tumor growth curve. Exponential tumor growth with exponential growth retardation. The vertical axis is tumor volume, and the horizontal axis is time.

exponential growth is not strictly maintained throughout the entire growth history. For example, if a skilled radiologist recognized a 0.5-cm tumor on a chest radiograph, or if a clinician palpated a 1-cm tumor mass, we might assume that the tumor had been detected quite early. In reality, the tumor has already undergone at least 30 doublings prior to detection, and this does not include any adjustment for ongoing cell loss.

Limited information exists regarding the actual doubling times of human tumors *in vivo* (14,15), as summarized in Table 13.1. For this historical analysis, tumors were relatively circumscribed and serially measured by radiographic imaging, often as pulmonary metastases. It is clear that embryonal tumors, lymphomas, and mesenchymal tumors have shorter doubling times than adenocarcinomas or squamous cell carcinomas. In addition, metastases generally have faster doubling times than their corresponding primary lesions.

The model also suggests other conclusions of clinical relevance. First, metastatic spread may occur well before obvious evidence of the primary lesion. Second, at later stages of tumor growth, a small number of doublings can produce a marked change in tumor size, with an increased potential for adverse clinical consequences. For instance, a 1-cm mass (at least 30 prior doublings) becomes a 4-cm mass after just 2 more doublings.

Host-Tumor Interactions

Ultimately, dysregulated growth exceeds local resources, and the tumor becomes dependent on the manipulation of host angiogenic pathways for delivery of oxygen, access to nutrients, and removal of waste products. Tumors generally grow without induction of host lymphatics and are characterized by increased interstitial pressures as a consequence of disordered capillary proliferation with leaky vessels and accumulation of extracellular fluid. Together, these factors result in regional hypoxia, acidosis, and necrosis that can limit the effective delivery of chemotherapy and

FIGURE 13.2. Theoretical tumor doubling curve assumes exponential tumor growth. The vertical axis is the number of cells, and the horizontal axis is the number of doublings.

may protect viable tumor cells that are more distant from functional capillaries. One of the potential benefits observed with anti-angiogenic therapy has been normalization of tumor vessels with reduced interstitial pressures and improved drug delivery (16).

Cell Cycle Kinetics

The kinetic behavior of individual tumor cells is also important in understanding tumor growth. Figure 13.3 is a schematic view

Table 13.1 Doubling Times of Human Tumors

Tumor Histology	Patients (n)	Doubling Time (Mean $\pm$ 2 SD, Days)
Embryonal tumors (lung metastases)	76	27 $\pm$ 5
Lymphomas	51	29 $\pm$ 6
Malignant mesenchymal tumors	87	41 $\pm$ 7
Squamous-cell carcinomas (lung metastases)	51	58 $\pm$ 9
Squamous-cell carcinomas (primary tumors)	97	82 $\pm$ 14
Adenocarcinomas (lung metastases)	4	83 $\pm$ 12
Adenocarcinomas (primary tumors)	34	166 $\pm$ 48

FIGURE 13.3. Phases of the cell cycle, beginning with M (mitosis) and proceeding through G₁ (postmitotic phase), S (DNA synthetic phase), and G₂ (premitotic phase). As G₁ becomes progressively longer, it is known as G₀.

of the cell cycle. Cells can remain in a noncycling postmitotic compartment (G₀) for extended periods of time, but retain the ability to reenter active cycling when triggered by growth factors or other local signals. The point of entry, or first gap phase (G₁), can be of variable length and associated with diverse cellular activities, including protein and RNA synthesis, DNA repair, and cell growth. After passing the first checkpoint in G₁, the cell enters the DNA synthetic phase (S), during which a complete copy of the cellular DNA is created through replication. The second gap phase (G₂) provides another opportunity for checkpoint control before entering active mitosis (M), during which the nuclear membrane disappears and the chromosomes condense (prophase) and align (metaphase) in conjunction with the appearance of the mitotic apparatus, consisting of microtubules, centrioles, and the kinetochore. Mitotic alignment is associated with one final checkpoint prior to actual separation (anaphase), followed by dissolution of the mitotic apparatus (telophase) and creation of daughter cells through cytokinesis. The postmitotic period (G₁) is variable, and cells can further differentiate, enter a noncycling state (G₀), or initiate another cycle.

Cell cycle events have important implications for the patient, tumor, and cancer therapist. Most chemotherapeutic agents disrupt DNA, RNA, or protein synthesis. Rapidly proliferating cells (i.e., short G₁) are most sensitive to chemotherapy, whereas cells that slowly proliferate (i.e., G₀ or long G₁) are generally less sensitive. Nondividing cells, such as the differentiated elements of a mature teratoma, may occupy space and contribute to tumor bulk and symptoms, but are relatively insensitive to chemotherapy.

Cell cycle times may be estimated by performing labeled mitotic curves *in vivo* or *in vitro*, and appear to be relatively similar for many solid tumors, with cycle times ranging from 10 to 31 hours (17). Compared with the tremendous variation in human tumor doubling times, this is a relatively narrow range, suggesting that the primary reason for variations in clinical tumor growth cannot be ascribed to variations in the cell cycle.

Growth fraction and programmed cell death also influence the overall tumor growth rate and response to therapy. The growth fraction is the proportion of tumor cells that are actively cycling. Often, these proliferating cells are located proximal to small blood vessels. Growth fractions in human tumors are quite variable, ranging from 25% to 95%. Although it may seem paradoxical, cell loss is usually very high in human tumors, ranging from 70% to more than 95%, and small changes in cell loss could produce major changes in apparent tumor growth (18).

Log Cell Kill

In principle, the rational use of chemotherapy relies on basic concepts of cellular kinetics, but the translation from preclinical models to solid tumors has been challenging. In animals, the curability of transplanted tumors is inversely proportional to the tumor cell number and size, and timing of treatment initiation. In part, this is the result of important tumor-host interactions, such as the time required to establish a blood supply. However, this is also an illustration of first-order cell-kill kinetics, whereby a constant fraction of exposed cells is killed, rather than a constant number. Using first-order kinetics, a single treatment for a tumor weighing 1 g (approximately 10⁹ cells) might yield 90% cell kill and would decrease the tumor population by only one log, leaving 10⁸ viable cells. Without further treatment, the tumor would grow back at a constant rate, with only a modest delay in lethality. Only when the log cell kill is very large (>99%) and repetitive can chemotherapy be curative or capable of reducing residual disease to less than 10⁴ cells. Certain cancers, such as choriocarcinoma, can be cured with a single application of a single drug. However, majority of cancers are intrinsically less sensitive and require multiagent chemotherapy over multiple cycles to achieve clinical benefit. Distribution of treatment over multiple cycles allows for host recovery while still achieving the cumulative cell kill required for tumor regression and cure.

Cell Cycle Specificity

Chemotherapeutic agents have complex mechanisms of action and can affect tumor cells through multiple pathways. Nevertheless, certain anticancer drugs are known to be proliferation-dependent and cell cycle-specific. Other drugs are cycle nonspecific, and are capable of killing in all phases of the cell cycle, generally without dependence on the proliferative rate. Examples of cycle-nonspecific drugs include alkylating agents, particularly nitrogen mustard, which are effective against a variety of solid tumors, including those with low growth fractions. Cell cycle-specific agents depend on the proliferative fraction of the tumor and phase of the cell cycle. A typical example is hydroxyurea, which inhibits ribonucleotide reductase. Not surprisingly, cell cycle-specific drugs tend to be more effective against tumors with a high proliferative rate and growth fractions. The interaction of specific cytotoxic agents with the cell cycle is summarized in Table 13.2.

PHARMACOLOGIC PRINCIPLES OF CHEMOTHERAPY

General pharmacologic principles should be considered by the physician in selecting individual drugs and managing their administration according to standards of dose and schedule. Many factors may influence the effectiveness and/or toxicity of chemotherapy, including absorption, distribution, metabolism, and excretion, as well as clinical complications, such as renal impairment, malnutrition, or drug-drug interactions.

Table 13.2 Relationship of Chemotherapy Agents to Intracellular Targets and Cell-Cycle Progression

Classification	Cell-Cycle Specificity	Cellular Targets and Mechanisms	Examples
Inhibition of DNA synthesis and repair	G ₁ , S	Inhibition of nucleotide synthesis and metabolism. Inhibition of thymidylate synthase, thymidylate phosphorylase, dihydrofolate reductase, ribonucleotide reductase	Antifolates (methotrexate, pemetrexed), nucleoside analogues (6-mercaptopurine, 5-fluorouracil, cytarabine, fludarabine, gemcitabine), hydroxyurea
	S	Stabilization of DNA-topoisomerase II cleavable complex, DNA intercalation, +/- free radical formation	Anthracyclines (doxorubicin, daunomycin, idarubicin, epirubicin), anthracenediones (mitoxantrone), epipodophyllotoxins (etoposide), actinomycin D
	S	Stabilization of DNA-topoisomerase I cleavable complex	Camptothecins (topotecan, irinotecan)
Alkylating agents and related compounds	G ₁ , G ₂ , S	Direct DNA damage, DNA adduct formation, free radical production, strand breakage	Radiation, platinum compounds (cisplatin, carboplatin, oxaliplatin), bleomycin, mitomycin C, nitrogen mustard, nitrosoureas, ecteinascidin
Antimicrotubule reagents	M	Inhibition of tubulin polymerization	Vinca alkaloids (vinristine, vinblastine, vinorelbine), colchicine
		Promotion of tubulin polymerization	Taxanes (paclitaxel, docetaxel), epothilones
		Kinesin spindle proteins	Investigational agents
Cell cycle agents	G ₁ , S, G ₂ , M	Mitotic checkpoint control, cyclin-dependent kinases (CDK), aurora kinases	Flavopiridol, investigational agents
Signal transduction modulators	G ₀ , G ₁ , S, G ₂	Growth factor sequestration, receptor blockade	Trastuzumab, cetuximab, pertuzumab, aflibercept, bevacizumab
		Inhibition of tyrosine kinase-mediated signal transduction	Erlotinib, gefitinib, dasatinib, imatinib, sorafenib, sunitinib, lapatinib
		Modulation of protein kinase C	Bryostatin, enzastaurin
		Inhibition of hormonal pathways	Tamoxifen, raloxifene, anastrozole, letrozole, fulvestrant, megestrol, mifepristone, flutamide, leuprolide
Gene regulation	NA	Gene regulation by inhibition of promoter methylation, DNA methyltransferase, or histone deacetylase	Azacitidine, suberoylanilide hydroxamic acid (vorinostat, belinostat)
Protein modifications	NA	Posttranslational protein modifications, inhibition of farnesylation	Tipifarnib, bisphosphonates
		Inhibition of the proteasome complex and clearance of ubiquitinated proteins	Bortezomib

Absorption, Distribution, and Transport

Drugs may be given orally, intravenously, intramuscularly, intra-arterially, or intraperitoneally. Selection of the route of administration depends on solubility, requirements for drug activation, local tissue tolerance, feasibility for an individual patient, and optimal tumor drug exposure, which is estimated as the area under the concentration time curve (AUC) for the drug and active metabolites. The ultimate effectiveness of any chemotherapeutic agent depends on optimizing the AUC at critical tumor sites. However, there are no established techniques for noninvasive measurement of active drug concentration at these critical sites, and we are forced to extrapolate tumor drug exposure from preclinical models and plasma concentrations over time. Techniques such as magnetic resonance spectroscopy and positron emission tomography can potentially provide information on drug distribution and tumor metabolism, but they require a substantial investment in technology and specialized reagents.

The increasing utilization of oral chemotherapy and development of oral molecular-targeted agents has renewed interest in bioavailability in the setting of meals and other factors that can modulate local intestinal transport. In most cases, initial dose and schedule guidelines from FDA-approved package inserts reflect data from large phase 3 trials, rather than smaller studies that might examine dietary or drug interactions. For example, the bioavailability of one tyrosine kinase inhibitor could be

increased over threefold in the setting of a high-fat meal (19), but the package insert recommends taking the drug on an empty stomach. With the high cost of chronic medication, it is apparent that there could also be substantial economic implications to these pharmacokinetic observations (20).

Some natural compounds, such as those found in grapefruit juice, can inhibit the cytochrome P450 isozyme CYP3A4 within the intestinal mucosa (21), as well as the drug efflux pump p-glycoprotein. Drugs that are substrates for either of these compounds can be more efficiently absorbed after ingestion of grapefruit juice, due to reduced local metabolism, leading to increased serum levels that may have clinical consequences, including cyclosporine, erythromycin, calcium channel blockers, and benzodiazepines.

The extent of drug binding to serum proteins, as well as physical properties, such as lipid solubility, diffusion, or molecular weight, may have an impact on tumor drug exposure. In addition, some areas of the body, particularly the brain, are actively protected from drug exposure and can serve as pharmacologic tumor sanctuaries, where small numbers of sequestered cancer cells may survive otherwise curative systemic therapy. Larger solid tumors eventually disrupt the blood-brain barrier, restoring access to conventional chemotherapy. In this manner, even drugs that are normally excluded from the central nervous system, such as carboplatin, can achieve dramatic reductions in metastatic disease (22).

In addition to achieving local delivery, most drugs must be internalized within tumor cells to achieve cytotoxicity. Internalization can be accomplished by passive diffusion, active transport, pinocytosis, or receptor-mediated endocytosis. Molecular targeting has also been utilized to enhance the delivery of conventional cytotoxic agents to tumors, based on expression of tumor-associated antigens, or the presence of specific receptors.

Many chemotherapeutic agents are lipophilic and highly protein bound in plasma, particularly to albumin. Commonly used agents with greater than 95% protein binding include cisplatin, paclitaxel, docetaxel, etoposide, and the active metabolite of irinotecan (SN-38). Agents with less protein binding include doxorubicin (75%), topotecan (35%), gemcitabine (10%), carboplatin (<5%), and ifosfamide (<5%). It is generally the unbound “free” drug that mediates toxicity, and any condition associated with variability in protein binding can have an impact on cumulative drug exposure. For example, the toxicity of chemotherapy is frequently accentuated in patients with poor nutritional status, which is associated with reduced protein levels and other metabolic changes (23). Docetaxel offers an interesting example for potential interactions, due to extensive binding to albumin, lipoproteins, and α -acidic glycoprotein (AAG), which has been correlated with changes in drug clearance, prompting further evaluation of optimized dosing (24).

Intraperitoneal Chemotherapy

Although most chemotherapy is administered by the systemic route, there are unique situations in which the regional use of chemotherapy has been studied, with intraperitoneal administration a specific example. If primary tumors or their metastases are anatomically confined to specific organs or particular regions of the body, or if unique pharmacokinetic circumstances exist that favor regional clearance, there is a theoretical rationale for regional chemotherapy. For example, intraarterial drug administration has been studied in cervical cancer, localized recurrence of rectal carcinoma, and head and neck cancer. Local complications are potentially serious, including arterial thrombosis, wound slough, lymphedema, and osteonecrosis caused by the shared arterial blood supply between the tumor and neighboring normal tissues. While high response rates can be achieved in selected patients, larger randomized trials are needed to evaluate overall risks and long-term outcomes.

Intracavitary chemotherapy has been used for tumors confined to the peritoneum, pleura, or pericardium. The rationale for this approach is based on the fact that clearance from a body cavity is delayed compared to the systemic circulation, achieving more prolonged exposure to higher regional concentrations of active agents. This technique has been most extensively studied in ovarian cancer, with evaluation of many agents, including 5-fluorouracil, doxorubicin, cisplatin, carboplatin, cytarabine, melphalan, etoposide, and paclitaxel (25,26). Phase 1–2 studies have uniformly demonstrated a pharmacologic advantage favoring the intraperitoneal compartment but have not documented enhanced drug delivery to actual sites of disease. Of key importance, penetration of peritoneal tumor nodules by passive diffusion is limited by fibrotic adhesions, tumor encapsulation, and high interstitial pressures, as a consequence of intratumoral capillary leak without functional lymphatic drainage. In addition, both cisplatin and carboplatin are rapidly cleared from the peritoneal compartment and recirculate through the blood, limiting the window for direct tumor penetration, exposing the host to systemic toxicity, and raising questions about the clinical importance of the local pharmacokinetic advantage. Based on these observations, it has been postulated that the major role for intracavitary therapy would be in patients with minimal residual disease.

Cisplatin has received the greatest attention for intraperitoneal delivery in ovarian cancer, including the management of

small-volume residual disease at the time of second-look laparotomy (27,28) and primary treatment of small-volume residual disease following initial cytoreductive surgery (29). In view of the risk of systemic nonhematologic toxicity from intraperitoneal cisplatin, there has been renewed interest in the substitution of intraperitoneal carboplatin, which differs in terms of reduced protein binding and increased overall time required for *in situ* activation (via aquation), with the possibility that clinical outcomes could be different between the 2 agents, and this is currently under investigation in a phase 3 randomized trial.

In contrast to cisplatin, paclitaxel is poorly absorbed from the peritoneal compartment, suggesting that patients might benefit from combined intravenous and intraperitoneal administration to optimize tumor drug exposure. As a single agent, intraperitoneal paclitaxel demonstrated a 61% pathology-confirmed complete response rate among 28 assessable patients with initial microscopic disease (30). However, only 1 of 31 patients (3%) with greater than microscopic disease achieved a complete response, emphasizing the limitations of drug access and penetration by diffusion from the peritoneal space.

Intraperitoneal therapy could also have an impact on the tumor-host relationship through alterations in local cytokine production, angiogenic response, or immunoregulation. Hopefully, future studies will evaluate some of these biologic parameters to assist with optimization of therapy. In this regard, it is also possible that intraperitoneal therapy could have clinical benefit regardless of the extent of disease, and current randomized trials have enrolled a subset of patients with suboptimal residual disease following primary cytoreductive surgery.

Biotransformation

Some agents, such as cyclophosphamide, ifosfamide, and capecitabine, are administered as true prodrugs and must undergo irreversible metabolism to the active form, most commonly in the liver, but also in tumor or other host tissues. For many of these agents, intraperitoneal or intraarterial administration would be ineffective, as it would achieve high local concentrations of the native compound, but without an opportunity for bioconversion. Other agents are in reversible equilibrium with reactive intermediates, such as irinotecan and SN-38 (7-ethyl-10-hydroxycamptothecin), with dependencies on local pH and presence of specific enzymes, such as carboxylesterase. Cisplatin and carboplatin both require activation through irreversible aquation to a reactive intermediary before they can initiate DNA adduct formation. Although the final reactive compounds are identical, the rate of aquation and adduct formation is much slower with carboplatin (31), but can be accelerated in the presence of activating nucleophiles, such as glutathione (32), even though the same nucleophiles can partially block cisplatin adduct formation at higher concentrations.

Renal Excretion and Physiologic Age

Drug inactivation, elimination, or excretion can dramatically influence cumulative exposure, which significantly affects antitumor activity and host toxicity. Inactivation and excretion of chemotherapeutic agents occurs primarily through the liver, kidneys, and body tissues, with lesser elimination through the stool. While any impairment of normal liver or kidney function can disturb drug metabolism and excretion, the most common problem encountered in the setting of gynecologic cancer is acute or chronic renal insufficiency due to tumor-mediated obstruction, drug-induced toxicity, advanced age, or preexisting comorbidities.

The use of combination chemotherapy in the elderly patient can pose a number of challenges related to bone marrow reserve and vital organ function (33). Although the risk of hematologic

FIGURE 13.4. Distribution of renal function in nondiabetic adults. Weighted distribution of predicted GFR (mL/min/1.73 m²) based on the MDRD formula from the Third National Health and Nutrition Examination Survey (NHANES III).

Source: From Clase CM, Garg AX, Kiberd BA. Prevalence of low glomerular filtration rate in nondiabetic Americans: Third National Health and Nutrition Examination Survey (NHANES III). *J Am Soc Nephrol*. 2002;13:1338–1349, with permission.

toxicity is generally increased, overall benefits from active chemotherapy regimens can still be demonstrated, as illustrated by the analysis of data from several breast cancer trials (34). Studies in ovarian cancer have indicated that age is an adverse prognostic factor, but there are insufficient data to determine how the benefits of treatment change with age. In part, this is related to the underutilization of chemotherapy in elderly patients (35) and reduced enrollment of elderly patients on clinical trials (36). From that perspective, it is important to define tolerable and effective treatment regimens that can be safely administered in elderly patients, incorporating supportive care, geriatric assessment, and adjustments for age-related changes in vital organ function (37).

In surveying the general nondiabetic female population, the incidence of moderate renal insufficiency dramatically increases with age, which is of particular relevance to the care of women with gynecologic cancer (38). For example, in the 60 to 69 year age group, over one-third of women have an estimated glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m² (Fig. 13.4). In addition, serum creatinine levels can be inappropriately low in women with gynecologic cancer, as a consequence of reduced muscle mass, malnutrition, post-operative recovery, or third-space fluid accumulation. In those settings, any of the standard formulae will overestimate GFR, with potential clinical consequences. Clearly, universal caution in dosing drugs with high renal clearance, especially carboplatin, is required.

Several methods are available to estimate GFR and classify the extent of renal injury based on age, sex, serum creatinine, and other factors (39–41). In general, serum creatinine is the dominant factor, and it remains unclear whether minor differences between formulae might have meaningful and/or consistent clinical consequences with regard to drug dosing. In most cases, it is sufficient to estimate GFR rather than obtain a precise measurement. However, all of these formulae are based on stable normalized biologic parameters and are less useful in the setting of dynamic changes following acute renal injury, or other nonrenal fluctuations in serum creatinine.

While urine collection for estimation of creatinine clearance (based on measured creatinine in the urine over a period of time) might appear to provide a better estimate of GFR, it is also subject to clinical variability, due to different rates of creatinine tubular secretion. Utilization of direct techniques to measure actual GFR, such as clearance of ⁵¹Cr-ethylenediamine tetraacetic acid (EDTA)

or inulin, remains the standard for comparison with indirect estimates, but these assays are rarely used in clinical practice due to cost and complexity.

Staging of chronic renal disease has been used to reflect overall severity and guide management decisions, including dose modifications. The most commonly used staging system is from the National Kidney Foundation (42). The formula derived from the Modification of Diet in Renal Disease (MDRD) study has been incorporated in standardized laboratory reports (39). However, the MDRD has not generally been validated for actual drug dosing. As a result, the Cockcroft-Gault (40) and Jelliffe (41) formulae are more commonly used for drug dose calculation (Table 13.3).

The situation has become further complicated by an international effort to recalibrate creatinine standards based on isotope dilution mass spectrometry (IDMS). These new standards have now been adopted by all major vendors and commercial laboratories. The relationship between old (pre-IDMS) and new (IDMS) creatinine values within the same patient is variable, depending on the specific vendor and equipment. In general, IDMS standards will lower the serum creatinine value by approximately 12%. Using the IDMS creatinine value will therefore increase the estimated GFR, and could lead to higher doses of chemotherapy, particularly carboplatin, with an impact on hematologic

Table 13.3 Commonly Utilized Formulae to Estimate Creatinine Clearance

Formula Name	Estimation of Creatinine Clearance (CrCl)
Cockcroft-Gault formula (40)	CrCl (mL/min) = (140 – age) × weight (kg) × (0.85 if female)/serum Cr (mg/dL) × 72
Jelliffe formula (41)	CrCl (mL/min) = [98 – [0.8 × (age – 20)]] × (0.9 if female)/serum Cr (mg/dL)
MDRD formula (39)	GFR (mL/min/1.73 m ²) = 170 × [serum Cr (mg/dL)] ^{–0.999} × (age) ^{–0.176} × (0.762 if female) × (1.180 if African American) × [SUN (mg/dL)] ^{–0.170} × [Alb (g/dL)] ^{+0.318}

Alb, serum albumin concentration; Cr, creatinine; GFR, glomerular filtration rate; MDRD formula, the Modification of Diet in Renal Disease study equation; SUN, serum urea nitrogen concentration.

toxicity (43). These changes prompted a review by the FDA, the National Cancer Institute (NCI), and the national cooperative groups, followed by distribution of safe initial dose recommendations in 2010 for patients enrolled in clinical trials, as modified below, incorporating recommendations from GOG (44):

- Safe initial dosing of carboplatin is based on using the Calvert formula with measured GFR, although estimated GFR is routinely employed in clinical practice.

$$\text{Carboplatin Total Dose (mg)} = \text{Target AUC (mg} \cdot \text{min/mL)} \cdot [\text{GFR} + 25] (\text{mL/min})$$

- Estimated GFR should be determined using a standard formula. The Gynecologic Oncology Group (GOG) currently recommends using the Cockcroft-Gault equation, although this formula was developed and validated for drug dosing using pre-IDMS creatinine values.

$$\text{Creatinine Clearance (mL / min)}$$

$$= \frac{[140 - \text{Age (years)}] \cdot \text{Weight (kg)} \cdot 0.85 (\text{for women})}{72 \cdot \text{Serum Creatinine (mg / dL)}}$$

- Actual body weight should be used for estimated GFR (Cockcroft–Gault) for patients with a body mass index (BMI) < 25. For obese patients (BMI > 25), GOG recommends using an adjusted weight.

$$\text{Adjusted Weight (kg)} = (\text{Actual Weight} - \text{Ideal Weight}) \cdot 0.40 + \text{Ideal Weight}$$

$$\text{Ideal Weight (kg)} = ([\text{Height in cm}/2.54] - 60) \cdot 2.3 + 45.5$$

- Due to abnormally low serum creatinine values, the estimated GFR can be nonphysiologic (falsely elevated) and should not exceed a maximum value of 125 mL/min. In addition, serum creatinine values for estimation of GFR should not be lower than a minimum value of 0.6 mg/dL (NCI) or 0.7 mg/dL (GOG). Using a maximum GFR of 125, the Calvert formula yields a maximum carboplatin dose of 900 mg at AUC = 6, or 750 mg at AUC = 5, or 600 mg at AUC = 4.

- After determination of a safe starting dose, subsequent modifications are based primarily on hematologic toxicity, or, in the event of a change in renal function, recalculation.

Specific guidelines exist for modifying drug doses for patients with renal impairment (45), with special attention to a growing list of agents with renal-dominant clearance (Table 13.4). Dosing parameters for patients on dialysis receiving individual drugs, such as cisplatin (46) and carboplatin (47), are also available. However, owing to the rapid introduction of new agents, clinicians are urged to consult updated prescribing information and online database resources.

Metabolism and Pharmacogenomics

Drugs can be metabolized in the liver, in other normal host tissues, or within tumors. Aside from those agents with extensive renal clearance, hepatic metabolism usually predominates. A large number of microsomal and cytoplasmic enzymes contribute to this process, with associated genetic polymorphisms that can account for individual variability in clearance, efficacy, resistance, and the risk of hepatic or nonhepatic toxicity. Techniques for screening and identification of pharmacogenomic elements are expanding, with potential implications for individualized drug selection, dosing, prediction of efficacy, and risk of toxicity.

Phase I reactions are characterized by attachment of polar groups to lipophilic compounds to facilitate water solubility, primarily through the cytochrome P450 superfamily of mixed function oxidases (CYP). Over 50 individual proteins have been

Table 13.4 Modifications in the Setting of Renal and Hepatic Dysfunction

Agents that Should Be Considered for Modification in the Presence of Moderate Renal Dysfunction	Agents that Generally Do Not Require Modification in the Presence of Moderate Renal Dysfunction	Agents that Should Be Considered for Modification in the Presence of Hepatic Dysfunction
Actinomycin D	Anastrozole	Docetaxel
Bleomycin	Bevacizumab	Doxorubicin
Capecitabine	Cabazitaxel	Epirubicin
Carboplatin	Cetuximab	Mitoxantrone
Cisplatin ^a	Docetaxel	NAB-paclitaxel
Cyclophosphamide	Doxorubicin	Paclitaxel
Etoposide	Epirubicin	PEG-liposomal doxorubicin
Hydroxyurea	Erlotinib	Vinblastine
Ifosfamide	Fluorouracil	Vincristine
Melphalan	Gefitinib	Vinorelbine
Methotrexate	Gemcitabine	
Pemetrexed	Irinotecan	
Topotecan	Letrozole	
	Leucovorin	
	Leuprorelin	
	Megestrol	
	Mitomycin	
	NAB-paclitaxel	
	Oxaliplatin	
	Paclitaxel	
	PEG-liposomal doxorubicin	
	Tamoxifen	
	Temozolomide	
	Trastuzumab	
	Vinblastine	
	Vincristine	
	Vinorelbine	

^aCan be administered at full doses in anephric patients receiving hemodialysis.

grouped into 18 families, with 3 families (CYP1, CYP2, and CYP3) that have evolved to handle the majority of exogenous agents. In particular, CYP3A4 catalyzes the biotransformation of more than half of our commonly used drugs (48), setting the stage for numerous drug-drug interactions.

Phase II reactions further increase water solubility by conjugation to a large polar entity, such as glucuronic acid, sulfate, acetate, glycine, glutathione, or a methyl group. These reactions result in the formation of nontoxic substances that can be excreted in the bile or urine. The predominant enzymes include UDP-glucuronyl transferases (UGT1 and UGT2), sulfotransferases, and glutathione S-transferases.

Phase III reactions directly promote biliary excretion mediated by transporter proteins, which are members of the adenosine triphosphate (ATP)-binding cassette (ABC) superfamily.

With awareness of polymorphisms in key enzymes, it has been possible to identify individuals with a dramatic increased risk of toxicity. For example, dihydropyrimidine dehydrogenase (DPD) controls the rate-limiting step in fluoropyrimidine metabolism, and approximately 10 variant DPD alleles occur with sufficient frequency to merit consideration of screening, as patients can be at risk for life-threatening mucosal injury and bone marrow suppression after receiving a single standard dose of 5-fluorouracil. While methods are available for screening, the potential reduction in risk needs to be balanced against the costs of a widespread screening program (49). Fluorouracil, or the pro-drug capecitabine, is not used in the primary treatment of gynecologic cancers, with the exception of some chemoradiation strategies and occasional palliative management of recurrent disease.

Uridine diphospho-glucuronosyl-transferase 1A1 (UGT1A1) is responsible for glucuronidation of bilirubin and a number of drug metabolites, most notably SN-38, the major active metabolite of irinotecan. As such, patients with a deficiency in UGT1A1 are at increased risk for life-threatening diarrhea and bone marrow suppression after receiving irinotecan and potentially other camptothecin derivatives with SN-38 metabolites (50). The UGT1A1*28 promoter mutation has been studied most extensively. However, mutations in the coding region can also occur, particularly in Asian populations, and may predict for efficacy in addition to toxicity (51). Gilbert's syndrome is associated with a mild unconjugated hyperbilirubinemia and reduced activity of UGT1A1 that is also associated with an increased risk of toxicity in both homozygous and heterozygous patients (52).

The ABC family of drug efflux proteins is also involved in biliary transport of camptothecins. Polymorphisms of ABCB1, also known as p-glycoprotein or multidrug resistance protein 1 (MDR-1) as well as ABCC2, also known as canalicular multi-specific organic anion transporter (cMOAT) or MRP2, appear to have an impact on the clinical efficacy and toxicity (neutropenia and diarrhea) associated with irinotecan therapy in Asian patients (53).

Dose modifications should be considered for patients with liver disease (54), particularly for paclitaxel, docetaxel, nanoparticle albumin-bound paclitaxel (55), doxorubicin, and the Vinca alkaloids (vincristine, vinblastine, and vinorelbine), which are primarily metabolized in the liver and/or excreted in the bile. Excessive toxicity may occur with doses that would ordinarily be acceptable, and guidelines for treating patients with impaired liver function should be consulted. However, variability in nonhepatic clearance, compensatory host adaptations, and interactions with other drugs, make these recommendations less reliable than those provided for patients with renal dysfunction. For example, dose reduction of etoposide in the setting of biliary obstruction remains controversial and may not be required (56).

Drug Interactions

During routine care, patients may receive a variety of drugs, including antiemetics, antihistamines (H_1 and H_2), steroids, nonsteroidal anti-inflammatory agents, anticoagulants, narcotics, and anti-infective agents. In addition, older patients are frequently receiving medication to manage underlying comorbidities, such as diabetes, hypertension, and elevated cholesterol. In view of the number and diversity of medications in common use, it is somewhat surprising that most interactions with cytotoxic chemotherapy appear to be of little consequence. However, prospective studies of chemotherapy administration in noncancer volunteers are impractical, and many potential interactions have not been fully explored. In fact, patients are likely to be excluded from enrollment on clinical trials on the basis of concomitant medications, rather than prospectively collecting valuable data to document safety or the need for treatment modifications. In clinical

practice, the occurrence of excessive hematologic and/or nonhematologic toxicity in an individual patient is usually attributed directly to the chemotherapy and managed with treatment modifications, rather than ascribed to a potential drug interaction.

When they occur, interactions can be critical, and some of the more important drug interactions are listed in Table 13.5. Particular attention should be placed on drugs that could alter renal function, such as aminoglycoside antibiotics, nonsteroidal anti-inflammatory agents, and diuretics, in patients with reduced fluid intake. Typical of *in vivo* interactions relevant in gynecologic cancer chemotherapy are the displacement of methotrexate from its transport protein by aspirin or sulfonamides, suppression of pseudocholinesterase by alkylating agents with increased apnea duration during succinylcholine-assisted general anesthesia, impairment of doxorubicin clearance by preadministration of paclitaxel, and impairment of paclitaxel clearance by preadministration of cisplatin.

Increased attention has been focused on drug metabolism and potential interactions with CYP isozymes, particularly CYP3A4, which has been linked to the metabolism of nearly half of all pharmaceutical agents (48). These interactions are guided by several common principles. Drugs that are *substrates* for the same isozyme may competitively inhibit metabolism, but these interactions are usually not of clinical consequence. Drugs that *directly inhibit* CYP isozymes without being a substrate for that isozyme are more likely to have clinical consequences. In this regard, itraconazole, ketoconazole, and fluconazole can inhibit CYP3A4 at low concentrations, and erythromycin can inhibit CYP3A4 via covalent binding and inactivation. Other drugs act as *inducers* of CYP isozymes by increasing gene expression or protein levels, such as glucocorticoids, barbiturates, and rifampin, which can increase the net activity of CYP3A4, resulting in decreased concentrations of susceptible compounds. In addition, many drugs that interact with CYP3A4 are natural products and may also interact with ABC family drug efflux pumps, including MDR-1. Among the anticancer agents that are substrates for CYP3A4 are cyclophosphamide, ifosfamide, docetaxel, etoposide, paclitaxel (also CYP2C8), docetaxel, vincristine, vinblastine, tamoxifen, and gefitinib (57). CYP2C9 and CYP2D6 are inhibited by imatinib, and doxorubicin can inhibit CYP2D6. Cyclosporine and verapamil can increase concentrations of doxorubicin and etoposide, probably through blockade of the P170 drug efflux pump (Table 13.6).

Owing to the diversity and rapid adoption of new compounds, information regarding drug interactions is best obtained from online databases, such as the Medical Letter (<http://www.medicalletter.com>), Micromedex (<http://www.micromedex.com>), the Drug Interaction Database from the University of Washington (<http://www.druginteractioninfo.org>), Medscape (<http://reference.medscape.com/drug-interactionchecker>), the package insert, or directly from the manufacturer.

DRUG RESISTANCE AND TUMOR CELL HETEROGENEITY

The curative potential of chemotherapy is limited by the emergence of drug resistance, which can be either intrinsic or acquired, and may involve one drug or multiple agents (pleiotropic resistance). Of interest, tumors with intrinsic or primary drug resistance to natural products often arise from duct cells or cells lining excretory organs (58). These cells, which normally detoxify, transport, and excrete a wide variety of toxic compounds, may retain these normal functions after transformation, manifesting as chemoresistance.

Intrinsic drug resistance is inferred based on clonal survival of tumor populations after initial chemotherapy exposure. Solid tumors are thought to consist of a mixture of clonal variants

Table 13.5 Physiologic and Pharmacologic Interactions in Cancer Chemotherapy

Physiologic Condition	Causation	Impact and Examples
Renal insufficiency	Obstruction, chronic kidney disease, hypovolemia, hypotension, nonsteroidals, nephrotoxins (aminoglycosides, cisplatin)	Decreased clearance of methotrexate, carboplatin, and other agents
Hepatobiliary dysfunction	Biliary obstruction, hepatitis, cirrhosis	Decreased clearance of doxorubicin, mitoxantrone, vincristine, vinblastine, etoposide, paclitaxel, docetaxel
	Gilbert's syndrome, impaired glucuronidation and polymorphisms (UGTA1A)	Increased exposure to SN-38 (from irinotecan)
	Decreased microsomal activity	Impaired activation of cyclophosphamide and ifosfamide
Reduced protein binding	Carrier displacement (sulfonamide, salicylates, phenytoin) Reduced carrier proteins (malnutrition)	Increased toxicity, higher free drug levels (methotrexate) Increased toxicity, higher free drug levels (cisplatin, paclitaxel, docetaxel, etoposide, SN-38)
Altered intestinal absorption	Oral antibiotics (neomycin)	Decreased absorption of methotrexate
	High-fat meal	Increased bioavailability of lapatinib Decreased bioavailability of capecitabine
	Grapefruit juice (intestinal CYP3A4 inhibition)	Increased bioavailability (cyclosporine, erythromycin, benzodiazepines)
Decreased metabolism	Caused by allopurinol Dihydropyrimidine dehydrogenase (DPD) deficiency	Delayed clearance of 6-mercaptopurine Lethal toxicity from 5-fluorouracil
Cholinesterase inhibition	Caused by cyclophosphamide	Decreased clearance of succinylcholine
Monoamine oxidase inhibition	Caused by procarbazine	Neurotoxicity and seizures (tricyclic antidepressants and phenothiazines)
MDR-1 competition	Associated with natural products and other substrates, including verapamil, cyclosporine, tamoxifen	Decreased efflux and increased toxicity from natural products (doxorubicin, vincristine, paclitaxel, docetaxel)
CYP2C9 Inhibition	Caused by capecitabine	Increased AUC of warfarin
CYP3A4 Induction	Caused by glucocorticoids, barbiturates, rifampin	Increased activation of cyclophosphamide
Inhibition	Caused by ketoconazole, itraconazole, fluconazole, erythromycin	Decreased metabolism of substrates (potentially significant)
Substrate competition	Caused by cyclophosphamide, ifosfamide, paclitaxel, docetaxel, etoposide, vincristine, vinblastine, tamoxifen, gefitinib	Decreased metabolism of other substrates (usually not clinically significant)

with different pre-existing mutations and patterns of resistance. Following repetitive cycles of chemotherapy, a process of clonal selection can occur, enriching for resistant populations, even while there could be a reduction in clinical tumor volume associated with elimination of more sensitive tumor elements.

Acquired resistance develops from cumulative somatic mutations, regulation of gene expression (including epigenetic processes), or other phenotypic alterations, over a period of time. From a clinical perspective, the end result of this process is indistinguishable from acquired resistance. However, acquired resistance is more likely to have a reversible component that could influence the timing and selection of subsequent chemotherapy. The most well-documented specific example is amplification of the dihydrofolate reductase (*DHFR*) gene, which is associated with acquired resistance to methotrexate (59). *DHFR* gene amplification is not generally observed prior to methotrexate exposure and can be reversed in the absence of drug exposure.

From the perspective of gynecologic oncology, there are 2 major patterns of drug resistance that emerge with continued treatment. The first is broad-based multidrug, or pleiotropic, drug resistance that has been associated with overexpression of *MDR 1* (P 170 glycoprotein) and/or other membrane-associated transport proteins (60,61). This multidrug resistance phenotype has maximal impact on natural products and their analogs, including the anthracyclines, Vinca alkaloids, and taxanes. The second is

resistance to alkylating agents, especially platinum compounds, mediated through a completely different set of cellular mechanisms, including reduced cellular uptake due to loss of membrane transport proteins, increased detoxification of reactive intermediates by glutathione production, increased damage tolerance due to defective detection and/or apoptotic signaling, and expanded capacity for DNA repair (62).

Multidrug Resistance

After exposure to a potential *MDR 1* substrate, tumor cells will develop cross resistance to a variety of structurally and functionally unrelated agents derived from natural products. This pleiotropic resistance is associated with increased drug efflux and a net lowering of intracellular drug concentration. Although relatively uncommon in newly diagnosed ovarian cancer (63,64), with increased utilization of natural products, including taxanes, etoposide, and liposomal doxorubicin, this pattern of resistance generally emerges over a period of time.

Other chemotherapeutic agents, including nucleoside analogues, are not substrates for *MDR 1* and remain unaffected by increased expression. In some resistant cell lines, a “collateral sensitivity” to gemcitabine has been observed, characterized by increased uptake and phosphorylation, which could be reversed

Table 13.6 Specific Mechanisms of Tumor Drug Resistance

Resistance Mechanism	Examples	Specific Cellular Target or Effects
<i>Impaired activation</i>	5-Fluorouracil	Reduced levels of thymidylate synthase, thymidylate phosphorylase, or dihydropyrimidine dehydrogenase
	Methotrexate	Reduced intracellular polyglutamation
	Doxorubicin	Low P450 enzymes
	Cyclophosphamide, ifosfamide	Decreased microsomal transformation
	Gemcitabine	Decreased deoxycytidine kinase
<i>Increased drug efflux</i>	Natural products	Increased <i>MDR 1</i> (P 170)
	Topotecan, mitoxantrone	Increased <i>BCRP</i> (ABCG2)
<i>Increased drug inactivation</i>	Alkylating agents, platinum	Elevated glutathione and other cellular thiols
<i>Accelerated DNA repair</i>	Alkylating agents, platinum, radiation	Induction of DNA repair enzymes
<i>Increased damage tolerance</i>	Alkylating agents, platinum, radiation	Loss of DNA mismatch repair
<i>Transport defects</i>	Melphalan	Reduced carrier-mediated uptake
	Gemcitabine	Decreased nucleoside transporter
	Platinum	Decreased copper transporter-1
<i>Target alterations</i>	Methotrexate	<i>DHFR</i> gene amplification
	Paclitaxel, docetaxel	Increased tubulin- $\beta 3$ isoforms or mutations
	Hydroxyurea, gemcitabine	Decreased ribonucleotide reductase
	Glucocorticoids	Decreased receptor binding
	Camptothecins	Decreased topoisomerase-I
	Anthracyclines, etoposide	Decreased topoisomerase-II

by verapamil, an inhibitor of *MDR 1* (65). This has not yet been validated in the clinical setting.

Other energy-dependent transporter proteins have been identified in resistant cell lines that may not overexpress *MDR 1*. These include the multidrug resistance-associated protein (MRP), which is representative of a family of cMOAT proteins (66). Similar to *MDR 1*, these proteins include multiple transmembrane domains but appear to have more broad tissue distribution and greater association with intracellular membrane-bound compartments. Another member of the family with relevance to gynecologic cancer is the breast cancer resistance protein (BCRP) or ABC protein G2 (ABCG2) that dimerizes to form a membrane-associated energy-dependent drug efflux pump responsible for atypical multidrug resistance following exposure to mitoxantrone or camptothecins, including topotecan. Overexpression of BCRP has been documented in ovarian cancer cells resistant to topotecan (67).

Platinum Resistance and DNA Repair

Although a number of DNA alkylating agents and radiation are used in the treatment of gynecologic cancer, platinum derivatives are the most important compounds in clinical practice. The dramatic success of platinum-based therapy is nearly overshadowed by the emergence of platinum resistance, and this observation has stimulated a substantial body of research over the last 35 years.

As a highly polar compound, cisplatin enters cells relatively slowly, and uptake can be influenced by local cation concentrations, pH, and the presence of reducing agents, prompting a search for membrane transporter proteins that could supplement passive diffusion. The major transporter involved in copper homeostasis, copper transporter-1 (CTR1), has now been shown to have a substantial role in cisplatin influx (68). Downregulation of CTR1 expression can reduce cisplatin uptake, leading to one mechanism of resistance. Targeted methods to safely and selectively increase platinum uptake in tumors are not yet available. However, it has been observed that ovarian cancer cell lines can rapidly downregulate membrane CTR1 after cisplatin exposure, followed by proteasomal-mediated degradation (69), suggesting that sequence and schedule of drug administration could have an impact on platinum uptake. JM-118, or cis-ammine-dichloro-cyclohexylamine-platinum (II), retains activity in tumor cells that have lost CTR1 (70). In that context, it is interesting to note that satraplatin (JM-216), an orally active carboplatin analogue that undergoes biotransformation to JM-118, has demonstrated promising activity in the treatment of prostate cancer (71).

Human ovarian cell lines resistant to alkylating agents, cisplatin, and irradiation contain elevated levels of cellular glutathione (GSH). Using resistant cell lines, it has been possible to demonstrate a restoration of drug sensitivity by exposure to the synthetic amino acid buthionine sulfoximine (BSO), which inhibits gamma-glutamylcysteine synthetase, causing GSH depletion (72). The exact mechanism by which GSH and other thiol compounds modulate cytotoxicity is unknown, although they can interfere with the formation of DNA-platinum adducts (73). There is also evidence of increased drug metabolism through GSH-linked transferases, which can vary for specific platinum compounds (74), and which may also contribute to cisplatin-mediated nephrotoxicity (75). Although clinical trials of BSO with melphalan have documented an 80% to greater than 90% reduction in tumor-associated GSH levels (76,77), this approach has not yet been demonstrated to improve the outcomes of platinum-based therapy.

In view of the prominent role of thiols in mediating a subset of platinum resistance, a sterically hindered platinum complex, picoplatin (JM473, ZD0473), was developed with the expectation that it would favor interacting with DNA rather than glutathione or metallothioneins (78). A phase 2 trial in recurrent ovarian cancer documented response rates of 8.4% in platinum-resistant disease and 32.4% in platinum-sensitive disease, similar to expectations with cisplatin or carboplatin (79). Of interest, there was no documented peripheral neuropathy or nephrotoxicity even in this group of patients with prior platinum therapy, implicating thiol reactions in the generation of these nonhematologic toxicities.

Enhanced capacity for DNA damage tolerance and repair can play a role in drug resistance to alkylating agents and cisplatin. Human ovarian cancer cell lines resistant to melphalan demonstrate increased ability to repair DNA, and this phenotype can be reversed by aphidicolin, a potent inhibitor of α and β DNA polymerase (80). Increased damage tolerance is another mechanism that contributes to resistance and is perhaps best illustrated by the mismatch repair system. Errors in DNA replication following platinum adduct formation can be detected by the postreplicative DNA mismatch repair system, which contains several well-characterized genes, including *MLH1* and *MSH2*.

Of note, cellular attempts to repair platinum alkylation by this mechanism are not successful, as the repair is directed at the nascent daughter DNA strand rather than the platinated parental strand. Eventually, abortive attempts at repair are associated with apoptotic cell death. Thus, loss of mismatch repair can actually promote cell survival by ignoring DNA damage in noncritical areas of the genome and has emerged as another mechanism of drug resistance.

Loss of *MLH1* or other mismatch repair genes is not uncommon in ovarian cancer and appears to increase after exposure to carboplatin or cisplatin (81). In addition, functional loss of *MLH1* activity in patients with ovarian cancer can also occur through hypermethylation-mediated silencing of the *MLH1* gene following exposure to platinum and has been correlated with poor survival (82). Preclinical models with platinum-resistant cell lines have shown improved treatment outcomes following exposure to 2'-deoxy-5-azacytidine (decitabine), which blocks DNA methylation, unmasking expression of *MLH1* (83). However, this can also result in increased hematologic toxicity, and novel strategies will be required to enhance the overall therapeutic benefit.

Oxaliplatin is one of several diaminocyclohexane (DACH) platinum derivatives that forms platinum adducts that differ in three-dimensional structure from the more established diamine compounds, such as cisplatin and carboplatin (84). As a consequence of these structural differences, oxaliplatin adducts are not detected by the mismatch repair system (85), and there was hope that oxaliplatin would retain clinical activity in patients with platinum-resistant tumors. However, in phase 2 studies, the response rate among ovarian cancer patients with less than a 6-month platinum-free interval was less than 7% (86,87).

Nucleotide excision repair (NER) is the primary mechanism to remove platinum-DNA adducts from genomic DNA. Excision repair cross-complementing 1 (*ERCC1*) is a critical gene on the NER pathway. Platinum resistance has been linked to *ERCC1* mRNA levels in tumors, including ovarian cancer (88). In lung cancer, immunohistochemical evaluation of *ERCC1* levels was also predictive for survival following cisplatin-based adjuvant therapy, with improved survival in patients with *ERCC1*-negative tumors (89). However, *ERCC1* may also have prognostic significance independent of chemotherapy, as patients assigned to observation with *ERCC1*-positive tumors had better survival compared to those with *ERCC1*-negative tumors (90). Randomized trials to prospectively assign chemotherapy for lung cancer based on *ERCC1* status have suggested that higher response rates can be achieved, but without a difference in progression-free or overall survival (91). The role of *ERCC1* as a prognostic or selective factor in women with ovarian cancer seems less clear (92).

The association between ovarian cancer risk and mutations in *BRCA1* and *BRCA2* sparked interest in DNA repair after it became apparent that patients with *BRCA1/2*-associated tumors had improved outcomes compared with patients with high-grade serous tumors without loss of *BRCA1/2* (93). These patients have tumors that are also more likely to respond to multiple lines of therapy with agents that target DNA, such as cisplatin, carboplatin, and doxorubicin, and this can be explained by the association of *BRCA1/2* with high-fidelity DNA repair pathways.

DNA repair can be targeted with inhibitors of poly (adenosine diphosphate [ADP]-ribose) polymerase (PARP), particularly in tumors with loss of *BRCA1/2* or other evidence of homologous recombination deficiency (HRD). The importance of these pathways is illustrated by the finding that tumors can develop a secondary mutation that partially restores *BRCA* function following exposure to PARP inhibitors, essentially reversing the drug sensitivity phenotype.

There are at least 2 distinct strategies for incorporation of PARP inhibitors in cancer chemotherapy. First, concurrent combinations of PARP inhibitors with platinum-based chemotherapy will increase platinum-mediated cytotoxicity, regardless of defects in homologous recombination repair. However, this

is not tumor specific, and has been associated with increased hematologic toxicity, requiring adjustments in dose and schedule to safely administer multiple cycles of chemotherapy. Second, PARP inhibitors can be administered as a single agent following completion of primary therapy, creating a synthetic lethal paradigm for tumors with HRD. In this regard, it is important to note that these defects are not simply limited to inherited mutations of *BRCA1* or *BRCA2*, but include somatic (intra-tumoral) mutations, methylation status, and mutations in other genes associated with DNA repair, exceeding 50% overall incidence in patients with high-grade serous or endometrioid histology, as reflected in data from The Cancer Genome Atlas project (94).

Clearly, in spite of considerable wide-ranging research, platinum resistance remains a major challenge in the treatment of gynecologic cancers, particularly high-grade serous ovarian cancer.

Taxane Resistance

In view of the prominent role of taxanes in the primary treatment of gynecologic cancers, a number of laboratories have explored pathways associated with taxane resistance. Overexpression of the drug efflux protein MDR-1 has been consistently associated with resistance to paclitaxel in cell lines in retrospective analysis of clinical outcomes (95). However, prospective clinical trials using an inhibitor of MDR-1 with paclitaxel, or with a combination of paclitaxel and carboplatin, failed to improve clinical outcomes (96,97).

Mutations in the β -tubulin subunit have been associated with paclitaxel resistance in preclinical models, but this does not appear to be a common clinical mechanism (98,99). Alteration in the proportion of tubulin- $\beta 3$ isoforms has been implicated in resistance to paclitaxel, while retaining sensitivity to nontaxane antitubulin agents, such as the epothilones (100). Expression of tubulin- $\beta 3$ has also been linked to cell survival pathways, with a potential impact on clinical outcomes (101).

Neither of these molecular mechanisms adequately explains the clinical behavior associated with paclitaxel therapy in women with ovarian cancer. For example, patients can still respond to paclitaxel on a weekly schedule after progressing within 6 months of receiving three-weekly paclitaxel as a component of primary therapy (102). Preclinical studies are examining a number of diverse pathways, including angiogenesis, cytokine networks, and microtubule-associated proteins (MAPs).

Other Mechanisms of Agent-Specific Resistance

A number of specific alterations have been identified in the setting of individual drugs (Table 13.6). For example, *DHFR* gene amplification was demonstrated in a patient with methotrexate-resistant ovarian cancer who had localized *DHFR* gene copies on an abnormally staining region of chromosome 4q (103). Methotrexate resistance has also been associated with defects in polyglutamation, limiting intracellular methotrexate accumulation (104). The action of nucleoside analogs, such as gemcitabine (2,2-difluorodeoxycytidine), is dependent on active membrane transport for uptake, which is followed by double phosphorylation and potential incorporation in DNA. This complex process offers several opportunities for development of resistance, such as decreased activity of specific nucleoside transport proteins or reduced phosphorylation by depletion of deoxycytidine kinase (105). In addition, the main enzymatic target of phosphorylated gemcitabine, the M2 subunit of ribonucleotide reductase, can undergo gene amplification in resistant cell lines (106) similar to the primary mechanism of resistance to hydroxyurea, an inhibitor of ribonucleotide reductase. Of interest, sensitivity to gemcitabine can actually be increased severalfold by prior exposure

to flavopiridol, an inhibitor of cyclin-dependent kinase activity, which has been shown to accelerate catabolism of the M2 subunit protein through the proteasome complex (107). Increased levels of target gene expression or protein, including thymidylate synthase, thymidylate phosphorylase, and dihydropyrimidine dehydrogenase, have also been associated with resistance to 5-fluorouracil in colon cancer, and have been correlated with clinical outcomes following 5-fluorouracil treatment (108,109). Even a superficial analysis of these specific examples would suggest potential strategies for screening of tumor tissue to guide the selection of optimal chemotherapy regimens, providing a basis for the application of tissue, gene, and protein arrays.

Tumor Profiling

Solid tumors have traditionally been considered to be a homogeneous collection of clonally derived cells with similar features, but it is now clear that tumors are composed of subpopulations with diverse biologic characteristics. Through genetic instability and epigenetic processes, such as gene promoter methylation and histone modifications, these subpopulations may exhibit different properties, with an impact on chemotherapy response. In addition, there can be variability in the potential for metastatic spread among cells that appear to be similar at a morphologic and genetic level (110). Recognition of tumor heterogeneity has altered our understanding of tumor behavior, with broad implications for multiagent and multimodality treatment programs.

Following the development of model systems for screening new anticancer compounds, it is not surprising that attention was focused on the process of screening actual human tumor cells for sensitivity and resistance to chemotherapy agents (111). A variety of methods have been developed utilizing clonogenic survival, ^3H -thymidine incorporation, vital dye exclusion, treatment of transplanted tumor xenografts, and colorimetric analysis of adenosine triphosphate levels. Although there is relatively good correlation between high-level resistance to individual agents demonstrated *in vitro* and lack of a clinical response *in vivo*, it is more difficult to predict sensitivity to specific agents, or to guide the utilization of drug combinations (112), reflecting tumor cell heterogeneity, assay complexity, and inability to evaluate the tumor-host relationship, including the impact of angiogenesis, cytokines, and immune response. A nonrandomized trial in recurrent ovarian cancer suggested good correlation between *ex vivo* assay sensitivity and clinical response (113), but this may be no better than selecting reasonable agents based on routine clinical factors, especially in the setting of recurrent disease. Importantly, there is a lack of prospective randomized data to validate these approaches, as well as concern for the cost and complexities associated with obtaining and shipping fresh tumor tissue.

With the rapid development of gene expression and proteomic arrays, mutational analysis, RNA sequencing, whole genome scanning, and whole genome sequencing, these questions have been carried to a new level of sophistication, as illustrated by The Cancer Genome Atlas project (94). In addition, as drug development has shifted toward molecular-targeted agents, there has been a request from FDA to incorporate predictive or selective biomarkers in regulatory filing, even though the cellular pathways and regulatory networks are not always well understood. Finally, large population-based molecular data repositories are under development, with the potential to rapidly identify targets, select patients, and evaluate new drugs without randomized trials, raising a number of interesting questions.

Dose Intensity and Density

The dose and frequency of drug administration can contribute to the overall effectiveness of a treatment regimen, as well as the

spectrum and severity of host toxicity. Dose intensity is a standardized measure of the amount of drug administered over time, most commonly expressed as mg/m^2 per week.

Preclinical studies demonstrate a sigmoidal relationship between dose and tumor response. This is characterized by a *lag phase* and a lower-limit *threshold* for observing benefit; a *linear phase*, where increases in dose are matched by improved efficacy; and a *plateau*, where toxicity continues to increase but there is no incremental improvement in response. In highly responsive tumors (e.g., choriocarcinoma, dysgerminoma), the entire dose-response curve is shifted to the left, with the result that standard chemotherapy doses are already situated near the upper plateau, and further dose increases are unlikely to achieve any improvement in clinical outcomes. In resistant tumors (e.g., previously treated cervical cancer), the curve is shifted to the right, and is also flattened, reducing the maximal potential benefit and increasing the risk of toxicity. For heterogeneous tumors with sensitive and resistant populations, such as epithelial ovarian cancer, it is unlikely that increased dose intensity would achieve long-term clinical benefit. However, lower-than-standard doses are potentially suboptimal, and arbitrary dose reductions or delays for nonphysiologic factors should be avoided. True dose-intense regimens have not been demonstrated to improve long-term clinical outcomes in women with gynecologic cancer, with the possible exception of recurrent germ cell tumors.

The dose intensity hypothesis has been extensively evaluated in the setting of advanced ovarian cancer, beginning with a series of retrospective reports (114). However, within practical dose ranges that can be achieved in the clinical setting, prospective randomized trials have not demonstrated significant improvements in either disease-free or overall survival (115). While frontline studies focused on platinum dose intensity, the question of paclitaxel dose intensity was also addressed in the setting of recurrent disease, again without evidence of improved outcomes.

Dose intensity is limited by acute (single-cycle) and cumulative (multicycle) nonhematologic and hematologic toxicity. Although multiple cycles of high-dose carboplatin and paclitaxel (with or without topotecan or gemcitabine) can be safely administered with hematopoietic progenitor and growth factor support, it is more difficult to overcome serious nonhematologic toxicities. Thus far, there is no evidence that a two- to three-fold increase in carboplatin dose intensity and cumulative dose delivery is associated with a substantial improvement in clinical outcomes (116–118), and it is unlikely that this approach will be further evaluated.

In contrast, there is renewed interest in “dose-dense” therapy, in which a series of 2 or 3 individual single agents are sequentially administered at maximal tolerated doses using short cycle intervals. This approach has been favorably evaluated in the adjuvant therapy of breast cancer (119), although it has not been clearly established if the clinical benefit is secondary to dose density or weekly scheduling of specific components. In ovarian cancer, the Japanese Gynecologic Oncology Group (JGOG) has conducted a phase 3 trial using standard scheduling of carboplatin together with weekly dose-dense scheduling of paclitaxel, with improved progression-free and overall survival (120), and other groups are working to validate and extend these observations. Overall hematologic toxicity was increased with dose-dense therapy, and it remains unclear if the therapeutic advantage is more dependent on optimal scheduling of paclitaxel, or the cumulative dose delivered. Short cycle intervals may offer a safer approach for intensification by reinforcing normal biologic rhythms that can accelerate repair and minimize host toxicity. For other drugs without known schedule dependence (such as cisplatin or carboplatin), weekly divided doses may not have a therapeutic advantage, and could possibly be less effective, due to lower peak serum concentrations.

GENERAL PRINCIPLES OF CHEMOTHERAPY

Treatment Objectives

Although certain general principles guide the clinician in choosing the appropriate classes of drugs or combinations, the decision to use these agents *at all* must be considered carefully. The critical factors involved in formulating a recommendation are reviewed in Table 13.7.

Natural History

Antineoplastic agents should be used only in patients whose malignancy has been established with pathologic confirmation, and with thoughtful consideration of the expected natural history, based on the primary tumor site, extent of disease, and rate of progression. Individual factors that could have an impact on tolerance for therapy must be evaluated in the context of treatment goals, including physiologic age (as reflected by vital organ function), general health, performance status, nutritional status, desire for treatment, and the presence of underlying illness. Prior history, including any previous cancer treatment and residual functional impairment, as well as patterns of recurrence, should also be considered. Finally, the emotional, social, and financial concerns of the patient and family must be respected (Table 13.7). Recommendations and goals should be presented to the patient and family in conjunction with a reasonable analysis of potential risks and benefits, which contributes to the process of informed consent and which should be followed by sharing of written information for future reference.

Clinical Assessment

Chemotherapy should not be instituted unless the physician is prepared to monitor tumor response (if applicable) carefully while managing expected and unexpected toxicities. If proper facilities are not readily available and the decision is made to begin therapy, the patient should be referred to a physician or facility that can provide integrated care.

Table 13.7 Important Considerations before Using Antineoplastic Drugs

Natural history of the malignancy

- Biopsy proof of malignancy
- Identification of primary site
- Rate of progression or grade
- Stage of disease, patterns of spread

Patient characteristics

- Physiologic age, nutritional status, performance status
- Vital organ function; bone marrow reserve
- Comorbid conditions
- Extent of previous treatment

Supportive care

- Adequate facilities to evaluate, monitor, and treat potential drug toxicities
- Emotional, social, and financial status; support from family
- Collaboration with referring physician

Treatment goals

- Parameters to monitor objective response to treatment
- Potential benefits
 - Curative intent
 - Improved or sustained quality of life
 - Control of disease
 - Palliation of symptoms

In view of the potential for serious toxicity, it is desirable to have some objective means of measuring tumor response by physical examination, radiographic imaging, and/or analysis of serum tumor markers. However, it is not uncommon to administer multiple cycles of adjuvant or postoperative chemotherapy without any direct means of documenting tumor response. In these circumstances, the physician should be alert for any clinical evidence of tumor recurrence or progression during treatment. In patients with evaluable disease, continued administration of chemotherapy requires verification of ongoing benefit.

Expectations

The likelihood of achieving long-term benefit influences the choice of treatment and the acceptance of potential toxicity. Primary tumors (and recurrence after surgical resection or radiation without prior chemotherapy) can generally be grouped according to the likelihood of achieving a durable response. However, chemotherapy is also being utilized more frequently in the setting of early-stage disease, including postoperative adjuvant therapy of ovarian cancer, concurrent chemoradiation in cervical cancer, and postoperative treatment (with or without sequential radiation) in endometrial cancer. While the use of chemotherapy in each of these scenarios is supported by data from phase 3 clinical trials, it is also apparent that research findings are often extended to populations with lower risk, and more patients are being exposed to platinum-based therapy at earlier points in their natural history, with an increased risk of treatment-resistant disease at the time of recurrence.

Most importantly, there is a group of tumors for which primary chemotherapy has been curative in the majority of patients, including choriocarcinoma and ovarian germ cell tumors. These patients should be treated aggressively with curative intent. Toxicity in this setting is acceptable, assuming that it is reversible, as the probability of long-term survival is high.

A second group, including advanced epithelial ovarian carcinoma, has high response rates to primary therapy (exceeding 75%), with prolongation of disease-free and median overall survival, but with only a modest improvement in overall mortality. Patients with these tumors usually benefit from therapy in terms of extended survival or quality-adjusted survival, and they should receive primary treatment at full doses unless contraindicated.

A third group of cancers, including advanced (or recurrent) endometrial cancer, cervical cancer, and uterine mixed Müllerian tumors, have intermediate or lower response rates to primary chemotherapy, with shorter duration of remission and limited improvement in overall survival. Treatment with an initial course of therapy is reasonable, with careful monitoring of toxicity and response.

Other tumors, including uterine leiomyosarcoma, are more resistant to primary therapy, achieving a low frequency of objective response without prolongation of survival. In this setting, the use of chemotherapy should be restricted and particular emphasis placed on including these patients in well-structured clinical trials to evaluate innovative treatments.

In patients with recurrent or progressive disease (PD) after prior chemotherapy, the expectations of response are reduced due to the emergence of drug resistance and the impact of prior therapy and/or disease on performance status and vital organ function. As such, treatment goals are usually palliative, with attention to quality of life and control of symptoms. In this population, the frequency of stable disease (SD) usually exceeds the objective response rate. With appropriate chemotherapy regimens that avoid cumulative toxicity, patients without further disease progression may remain on therapy for prolonged periods of time with an acceptable quality of life. Most patients are best managed with single-agent chemotherapy with regular assessment of ongoing response and management of toxicity. However, patients with epithelial ovarian cancer and a

prolonged treatment-free interval generally receive a platinum-based combination.

The decision to embark on antineoplastic drug therapy is obviously complex. Optimal patient care demands careful review of the multiple factors affecting therapy to maximize any opportunity for improving survival and quality of life.

Choice of Specific Chemotherapeutic Regimens

After the decision to use chemotherapy has been made, the appropriate regimen must be selected. The physician is aided in this task by the results of randomized trials and evolving standards of care, including published practice guidelines. However, not every patient can receive “standard” therapy because of idiosyncratic reactions, vital organ dysfunction, prior treatment, or other factors. Practical individualized decisions are facilitated by the logical grouping of chemotherapeutic agents in several classes with similar pharmacologic properties, mechanisms of action, and spectrum of toxicity. The most important classes are the platinum-based alkylating agents, nonplatinum alkylating agents, antimetabolites, antitumor antibiotics, antimicrotubule agents, nucleoside analogs, hormones, and newer molecular targeted therapies.

A number of combination regimens have been evaluated in the management of gynecologic cancer, and some have been widely adopted as “standard of care” for primary management of advanced-stage or recurrent disease. Phase 3 trials have demonstrated the superiority of specific regimens, such as paclitaxel with either cisplatin (121) or carboplatin (122) in ovarian cancer; a triplet combination of paclitaxel, cisplatin, and doxorubicin with granulocyte colony-stimulating factor (G-CSF) in endometrial cancer (123); cisplatin with either paclitaxel (124) or topotecan in cervical cancer (125); and ifosfamide with paclitaxel in uterine mixed Müllerian tumors (126).

However, none of the standard combinations for advanced ovarian, endometrial, or cervical cancer has been directly compared to sequential therapy with the best active single agents, and the superiority of combination therapy has not been fully established. In the setting of ovarian cancer, phase 3 trials have suggested that sequential therapy with platinum followed by paclitaxel may offer similar long-term outcomes to a combination of platinum and paclitaxel (127,128). Although the initial frequency of tumor response is often increased with combination therapy, long-term outcomes such as overall survival and symptom-adjusted quality of life can be similar for patients who receive optimal sequential therapy with single agents. This is primarily related to the advanced stage of disease at the time of initial treatment with systemic chemotherapy and the lack of curative therapy for the majority of patients. As such, if individual patient circumstances contraindicate the use of a standard combination regimen, it remains a reasonable option to begin therapy with one of the active single agents. In addition to their application as primary therapy for advanced disease, combinations can also be employed as adjuvant therapy for patients with early-stage disease at increased risk for recurrence and for patients with late recurrence after good response to initial therapy.

Adjuvant chemotherapy refers to the initial use of systemic chemotherapy after surgery and/or radiation therapy has been performed with curative intent and there is no evidence of residual disease. Adjuvant chemotherapy is considered if the subsequent risk for recurrence after initial definitive therapy is relatively high (generally greater than 20%), but it is not routinely recommended when the risk of recurrence is less than 10%. In the adjuvant therapy of epithelial ovarian cancer, long-term results from randomized trials have documented a reduction in the risk of recurrence after platinum-based chemotherapy (129,130). However, in carefully staged patients (to exclude occult advanced-stage disease),

it has been difficult to establish an advantage in overall survival. Phase 3 studies in endometrial cancer (131) and uterine mixed Müllerian tumors (132) have documented improved survival with the use of adjuvant combination chemotherapy compared to whole abdomen radiation in selected patients with high-risk disease, increasing the overall proportion of patients who receive adjuvant therapy.

Concurrent chemotherapy with radiation (chemoradiation) refers to the use of chemotherapy to sensitize the tumor to the effects of radiation delivered with curative intent. This has been most extensively studied in the primary management of locally advanced cervical cancer, where platinum-based chemoradiation has been proven to be superior to radiation alone (133). In general, the duration of chemotherapy coincides with the duration of external beam radiation. Although the preferred weekly dose of cisplatin might appear to be low, these regimens generally exceed the overall dose intensity of cisplatin when used to treat advanced disease, and patients require monitoring to avoid cumulative toxicity and treatment interruptions.

Neoadjuvant chemotherapy generally refers to the use of chemotherapy in the management of locally advanced disease in situations where it would be difficult or impractical to perform immediate surgery or radiation. Following a response to initial chemotherapy, there is an expectation that morbidity associated with the overall treatment program can be minimized in conjunction with a reduction in radiation treatment volume or extent of surgery. This approach is most often considered in advanced cervical cancer, where high initial response rates to neoadjuvant therapy have been observed. However, the long-term benefit of this approach has not been established. Neoadjuvant therapy is also a consideration in advanced ovarian cancer, particularly in patients with large-volume ascites, pleural effusions, diffuse small-volume disease, or comorbidities that might increase surgical risk (134). In this setting, it has been difficult to conduct randomized neoadjuvant trials owing to impaired performance status, the desire to establish a definitive tissue diagnosis, and the bias toward initial cytoreductive surgery.

Monitoring of Tumor Response

Generally accepted criteria for evaluation of responses are necessary to facilitate treatment decisions and comparisons among different regimens. Several standards have been used, including those developed by the World Health Organization (WHO). However, in 2000, an international working group including the European Organization for Research and Treatment of Cancer (EORTC), the National Cancer Institute of Canada (NCIC), and the National Cancer Institute (NCI) of the United States developed, validated, and published new Response Evaluation Criteria in Solid Tumors (RECIST 1.0), which were widely adopted within clinical trials and updated as RECIST 1.1 in 2009 (135).

RECIST is based on the prospective designation of measurable lesions, ≥ 10 mm in one dimension (longest axis) on computed tomographic (CT) imaging, and at between 1 and 5 “target lesions” that can be reproducibly measured to determine tumor response, as well as “nontarget lesions” that are used to corroborate response. Lymph nodes represent a special category, as normal anatomic structures, and must be ≥ 15 mm on the short axis to qualify as a measurable or target lesion. Helical CT and magnetic resonance imaging (MRI) are the preferred techniques to monitor tumor response, and the same technique that is used for initial assessment should be used for subsequent measurements. With the expanding use of positron emission tomography (PET) and merged PET-CT imaging, it is important to note that PET data are not included in RECIST, but the CT component of a PET-CT study can be used for RECIST if the CT is of sufficient diagnostic quality. The use of physical examination is restricted to cutaneous lesions or superficial adenopathy that

can be directly measured with calipers. The omission of findings on bimanual pelvic examination poses a particular challenge for monitoring regional disease in patients with gynecologic tumors, and most of these findings would be categorized as nontarget lesions, unless confirmed on radiographic imaging. An overview of RECIST determinations is provided in Table 13.8.

The summary response designation within RECIST integrates the findings from target and nontarget lesions, as well as serum tumor markers (if applicable). Serum tumor markers are not sufficient to declare response but, if initially elevated, must normalize to designate a complete response. International criteria to declare disease progression on the basis of a serial elevation in CA-125 have been widely adopted (136,137), but there is incomplete agreement on criteria to define a partial response during treatment (138). Changes in CA-125, alone, without other evidence of disease, are not recognized within the RECIST paradigm and

Table 13.8	Evaluation of Overall Disease Response (Recist 1.1)
Complete Response (CR) ^a	Disappearance of all <i>target</i> ^b and <i>nontarget</i> lesions, absence of new lesions, and normalization of tumor marker levels (if appropriate). Pathologic lymph nodes must have a reduction in short axis to <10 mm.
Partial Response (PR)	Disappearance of all <i>target</i> lesions, without progression of <i>nontarget</i> lesions, without appearance of new lesions, and with persistence of abnormal tumor marker levels. Or At least a 30% decrease in the sum LD of <i>target</i> lesions (taking as reference the baseline sum LD) without progression of <i>nontarget</i> lesions or appearance of new lesions.
Progressive Disease (PD)	At least a 20% increase in the sum LD of <i>target</i> lesions, taking as reference the smallest sum LD recorded since the start of treatment, or the appearance of one or more new lesions, or progression of any <i>nontarget</i> lesion. The sum LD must demonstrate an increase ≥5 mm.
Stable Disease (SD) ^c	Neither sufficient shrinkage of <i>target</i> lesions to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the start of treatment. No appearance of new lesions (<i>target</i> or <i>nontarget</i>).

Note: Measurable lesions can be accurately measured in at least one dimension with longest diameter (LD) ≥20 mm using conventional radiography, or ≥10 mm with spiral CT scan, or ≥10 mm with calipers on physical exam. Lymph nodes must be ≥15 mm along the short axis to be considered pathologic or measurable. *Nonmeasurable lesions* consist of all other lesions, including small lesions (longest diameter <20 mm with conventional imaging techniques or <10 mm with spiral CT scan), bone lesions, leptomeningeal disease, ascites, pleural/pericardial effusion, inflammatory breast disease, lymphangitis, cystic lesions, and abdominal masses that are not confirmed or followed by imaging techniques.

^aTo be assigned PR or CR, changes in tumor measurements must be confirmed by repeat assessments no less than 4 weeks after the criteria for response are first met. The duration of overall response is measured from the time that criteria are met for CR or PR (whichever status is recorded first) until the first date that recurrence or PD is objectively documented, taking as reference for PD the smallest measurements recorded since the treatment started.

^bTarget lesions include measurable lesions up to a maximum of 2 lesions per organ and 5 lesions in total, representing all involved organs, selected on the basis of size (lesions with the longest diameter) and suitability for accurate repeated measurements.

Nontarget lesions include all other lesions (or sites of disease) to be identified and recorded at baseline. Serial measurements of these lesions are not required, but the presence or absence of each should be noted throughout follow-up. ^cIn the case of SD, follow-up measurements must have met the SD criteria at least once after study entry at a minimum interval (in general, not less than 6 to 8 weeks) that is defined in the study protocol. SD is measured from the start of the treatment until the criteria for disease progression are met, taking as reference the smallest measurements recorded since the treatment started.

are not validated for seeking regulatory approval of new treatments. Overall, RECIST is more detailed and specific than previous response criteria, and is also more demanding of the clinical team and radiologist, particularly if there are a large number of target and nontarget lesions.

Complete Response (CR) refers to the complete disappearance of all objective evidence of tumor, including normalization of tumor markers, and a resolution of all signs and symptoms referable to the tumor. Complete regressions of cancer are generally those associated with a prolongation of survival.

Partial Response (PR) refers to at least a 30% decrease in the sum of the longest diameter of all measurable lesions (shortest diameter for lymph nodes). Usually, this would be accompanied by some degree of subjective improvement and the absence of any new lesions during treatment. Partial remissions are generally accompanied by improved well-being for a period of time but are not expected to improve overall survival. A variety of terms have been used to designate lesser responses (e.g., minor response, objective regression), but these are rarely associated with any significant clinical benefit.

Progressive Disease (PD) is defined as a 20% or greater increase in the sum of the longest diameter of all measurable lesions (shortest diameter for lymph nodes) or the appearance of new lesions. Note that measurements refer to the shortest value in prior measurements, not necessarily the measurements obtained prior to initiating treatment.

Stable Disease (SD) is the term applied to patients without measurable tumor response or progression fitting one of the prior criteria. Disease stabilization is an acceptable goal in the setting of palliative therapy for recurrent disease provided that symptoms have not progressed and the patient can tolerate continued therapy.

Changes in the volume of ascites or pleural fluid are not usually considered in the measurement of response, as a number of factors unrelated to cancer can influence third-space fluid accumulation, such as nutritional status, renal function, and treatment-related toxicity. However, appearance of a new fluid collection with cytologic verification would represent PD. Similarly, the appearance of new symptoms, such as a partial small bowel obstruction, does not always indicate progression of disease but could be related to prior surgery, irradiation, chemotherapy, or infection. In general, it is preferable to base decisions regarding treatment on objective measures of response, as described, rather than subjective findings or symptoms. Overall monitoring of small-volume intraperitoneal, diaphragmatic, or intrapleural disease is not adequately addressed within RECIST, and practical modifications have been proposed for patients with mesothelioma (139).

MANAGEMENT OF CHEMOTOXICITIES

Dose Selection, Toxicity Assessment, and Supportive Care

Chemotherapeutic regimens are universally toxic, with a narrow margin of safety, and it is generally necessary to adjust individual doses in accordance with patient tolerance. Initial dosing is derived from body surface area, weight, renal function, and hepatic function. However, there are a number of other factors that could further influence tolerance, including nutritional status, performance status, extent of disease, exposure to prior therapy, third-space fluid accumulations, metabolic polymorphisms, and uncharacterized drug interactions. Current dose algorithms generally fail to address these factors, although emerging pharmacodynamic and pharmacogenomic research has improved individualized dosing in selected cases.

Optimal dosing in obese patients has been questioned, as the distribution and metabolism of drugs within adipose tissue could vary from other compartments. Obesity is also a risk factor for cancer development and is common in the setting of endometrial cancer. In addition obesity is associated with a number of other comorbidities or metabolic conditions that could alter drug kinetics or the risk of toxicity. For these reasons, and in view of toxicity observed within previously radiated endometrial cancer patients, GOG has previously capped the body surface area (BSA) used for initial drug dosing to a value of 2.0 m². However, actual data to reinforce this decision are limited (140), and a recent guidelines panel recommended that obese patients should receive full weight-based dosing without arbitrary reductions or caps (141).

Consistent and standardized monitoring of host toxicity will help to avoid life-threatening events and assist in the implementation of dose adjustments. The Cancer Therapy Evaluation Program (CTEP) of the NCI has developed a detailed and comprehensive set of guidelines for the description and grading of acute and chronic organ-specific toxicity in collaboration with the FDA, international cooperative groups, and the pharmaceutical industry. Most clinical research protocols have incorporated these criteria, which are also applicable to the grading of toxicity for standard chemotherapy regimens outside of a clinical trial. The current version of the Common Terminology Criteria for Adverse Events (CTCAE) is available in electronic format from CTEP (<http://ctep.cancer.gov/protocolDevelopment/>). Basic hematologic parameters from CTCAE version 4 have been summarized in Table 13.9.

An unintended consequence of our current regulatory environment is that most new medications receive single-agent FDA approval at a dose and schedule that is close to the maximally tolerated dose (MTD), increasing the likelihood of host toxicity, particularly when administered over multiple cycles. The association between dose and toxicity is usually dramatic at levels close to the MTD. As such, a modest reduction in dose or an adjustment in schedule can have a substantial impact on acute and cumulative toxicities. The impact of these minor modifications on efficacy is generally unknown, but unlikely to be as dramatic as the impact on toxicity, and many clinicians frequently make modifications in the starting dose and/or schedule of single agents

or combinations, essentially deviating from FDA-approved indications. As these modifications become integrated with clinical practice, limited supporting data emerge, usually from nonrandomized trials, but the primary FDA-approved dose and schedule is rarely changed. Many agents in common use today, including polyethylene glycol (PEG)-liposomal doxorubicin, topotecan, paclitaxel, docetaxel, and gemcitabine, are frequently modified in accord with emerging clinical experience, but without changes in the FDA-approved regimen. It is thus important for the clinician to be aware of emerging data, as well as data from pivotal trials that were used to support original FDA registration.

In view of the narrow safety margin for chemotherapy, it is important that all orders be reviewed by a nurse and pharmacist with oncology experience. Height, weight, calculation of body surface area, ideal weight adjustments (if appropriate), pertinent laboratory values, and methods of dose calculation should be clearly indicated and verifiable. Templated orders encourage systematic review and can reduce the risk of error. In addition, it is preferable to have defined dose levels to account for expected treatment modifications rather than relying on percentage-based modifications. For example, it is not always obvious if a percentage refers to the degree of dose reduction or the amount of drug to be administered, which becomes compounded over multiple cycles, with the potential for more than one modification. One convenient method of structured dose modification is illustrated in Table 13.10. With this approach, modifications for the subsequent course of therapy are implemented according to the

Table 13.9 CTCAE Grading of Myelosuppression

Adverse Event Terminology	Grade			
	1	2	3	4
White Blood Cell Decreased (per mm ³)	LLN to 3,000	<3,000 to 2,000	<2,000 to 1,000	<1,000
Neutrophil Count Decreased (per mm ³)	LLN to 1,500	<1,500 to 1,000	<1,000 to 500	<500
Anemia (Hemoglobin) (g/dL)	LLN to 10.0	<10.0 to 8.0	<8.0; transfusion indicated	Life-threatening consequences, urgent intervention indicated
Platelet Count Decreased (per mm ³)	LLN to 75,000	<75,000 to 50,000	<50,000 to 25,000	<25,000

LLN, lower limit normal (institutional).

Table 13.10 Representative Drug Dose Modifications for Hematologic Toxicity

Category (Timing)	Parameters	CTCAE Grade	Dose or Schedule Modifications
Granulocytes (day of therapy)	>1,500/mm ³	0, 1	Full doses of all drugs.
	<1,500/mm ³	2, 3, 4	Delay until recovered. If delay >7 days, reduce doses by one level or add G-CSF. If delay >14 days, reduce doses by one level and add G-CSF.
Platelets (day of therapy)	WNL	0	Full doses of all drugs.
	< LLN to 75,000/mm ³	1	Delay until recovered.
	<75,000/mm ³	2, 3, 4	Delay until recovered. If delay >7 days, reduce doses by one level.
Granulocytes (cycle nadir)	>1,000/mm ³	0, 1, 2	Full doses of all drugs.
	<500/mm ³ for ≥7 days	4	Reduce doses by one level. If already reduced, add G-CSF for future cycles.
	<1,000/mm ³ with fever	3, 4	Add G-CSF for current episode, reduce doses by one level for future cycles. If already reduced, add G-CSF for future cycles.
Platelets (cycle nadir)	≥50,000/mm ³	3	Full doses of all drugs.
	<50,000/mm ³ with bleed	3, 4	Reduce doses by one level.
	<25,000/mm ³	4	Reduce doses by one level.

CTCAE, Common Terminology Criteria for Adverse Events; G-CSF, granulocyte colony-stimulating factor; LLN, lower limit normal; WNL, within normal limits. Dose reductions for individual drugs within a combination regimen should be based on the likelihood that a particular drug contributes to the observed hematologic toxicity.

degree (grade), duration, and timing of toxicity experienced during the preceding course. Although treatment can be delayed on a week-by-week basis to allow for recovery, delays of greater than 2 weeks should be avoided through dose modification and utilization of hematopoietic growth factors. With expanded utilization of combination regimens, it is also helpful to know the patterns of toxicity associated with individual drugs, as it might be appropriate to modify one component rather than an entire regimen.

Bone Marrow Toxicity

Bone marrow toxicity is the most common dose-limiting side effect associated with cytotoxic drugs, and neutropenia is the most common manifestation of bone marrow toxicity, occurring 7 to 14 days after initial drug treatment and persisting for 3 to 10 days. CTCAE grading criteria are summarized in Table 13.9. For purposes of dose modification, the absolute neutrophil count (ANC) is preferred over total white blood count, as this more accurately reflects dose tolerance and risk of infection, which parallels the duration of grade 4 neutropenia ($ANC \leq 500/mm^3$). Dose-limiting thrombocytopenia is less common than neutropenia, but has become more frequent with wider utilization of carboplatin and carboplatin-based combinations. A systematic approach to management of hematologic toxicity can help to reduce the risk of error and facilitate overall compliance with a treatment regimen (Table 13.10).

Radiation, alkylating agents (e.g., melphalan, carboplatin), and other DNA-damaging agents (e.g., nitrosoureas, mitomycin C), can have cumulative long-term effects on bone marrow reserve. Most other agents, including the taxanes and topotecan, show no evidence of cumulative toxicity and can be administered for multiple cycles without dose modification.

In view of the frequent occurrence of neutropenia and the risk of infectious complications, utilization of G-CSF, including filgrastim or the longer-acting PEG-filgrastim, has increased. Although these agents promote more rapid granulocyte recovery, thus avoiding potential complications and facilitating the maintenance of dose intensity, their use has not been shown to improve long-term survival for patients with gynecologic cancer, compared to conservative management with dose reduction and cycle delay. In addition, G-CSF is not effective in the management of thrombocytopenia and may actually increase the degree of thrombocytopenia by diversion of immature marrow elements, a particular problem after multiple cycles of carboplatin. Recombinant megakaryocyte growth factor is an option to maintain platelet counts (142). However, current treatment programs are not associated with a high frequency of complicated grade 4 thrombocytopenia, and the value of aggressive support would appear to be limited.

Moderate degrees of anemia are quite common in cancer patients receiving chemotherapy, which may contribute to chronic fatigue. With increased recognition of blood-borne viral pathogens and limited supplies of banked blood, frequent transfusions are not practical or recommended, and many patients will adapt to chronic anemia with minimal symptoms. The availability of recombinant erythropoiesis-stimulating agents (ESA), including erythropoietin (epoetin alfa) and darbepoietin, has provided a generally safe and effective alternative for the management of anemia associated with chemotherapy (143) and should be considered on a case-by-case basis, although financial costs at the recommended dose and schedule can be greater than the intermittent use of blood products (144). Emerging data with regard to the potential risks associated with ESA, including cardiovascular events, thrombosis, and reduced tumor-related survival in placebo-controlled, randomized trials (145), have prompted the FDA to reevaluate the role for ESAs in routine practice and to implement specific Risk Evaluation and Mitigation Strategies (REMS) that require physician training, registration, and

auditing (146,147). A Medicare National Coverage Determination also limited reimbursement to patients with confirmed hemoglobin of >10 g/dL (148). Patients with anemia should undergo evaluation of iron stores, with appropriate use of iron replacement, prior to initiation of ESA.

Gastrointestinal Toxicity

Most anticancer agents are associated with some degree of nausea, vomiting, and anorexia. There are 3 major categories of nausea and vomiting: *anticipatory*, occurring prior to actual administration of chemotherapy; *acute onset*, beginning within 1 hour of chemotherapy administration and persisting for less than 24 hours; and *delayed*, beginning more than 1 day after chemotherapy administration and persisting for several days. Prophylactic management of these adverse effects improves patient acceptance and facilitates completion of therapy with full doses on schedule.

The antiemetic regimen is tailored to the emetogenic potential of the treatment, which reflects the incorporation of specific drugs, as well as the dose and schedule of drug administration. Mild nausea and vomiting can often be managed effectively with H_1 antihistamines (diphenhydramine), phenothiazines (prochlorperazine or thiethylperazine), butyrophenones (haloperidol), steroids (dexamethasone or methylprednisolone), benzamides (metoclopramide), or benzodiazepines (lorazepam). These are likely to be sufficient with drugs such as bleomycin, docetaxel, paclitaxel, Vinca alkaloids, 5-fluorouracil, methotrexate, mitomycin C, gemcitabine, PEG-liposomal doxorubicin, and topotecan.

For drugs with more severe emetogenic potential, including cisplatin, carboplatin, cyclophosphamide, or dactinomycin, a more aggressive prophylactic regimen is required. In general, these patients should receive a 5-hydroxytryptamine (5-HT₃) receptor antagonist, such as ondansetron or granisetron, prior to chemotherapy and repeated at 8- to 12-hour intervals. Both compounds are also available in an oral formulation, which has been helpful in the management of delayed and/or chronic nausea after chemotherapy or nausea associated with multiday oral chemotherapy regimens. Longer-acting 5-HT₃ antagonists have also become available, including palonosetron and dolasetron, which require only a single intravenous or oral dose prior to chemotherapy. As a group, the 5-HT₃ antagonists have been quite effective in controlling severe emesis, with few side effects, but are more expensive than prochlorperazine (149). Chronic nausea and vomiting can be a particular problem after several cycles of cisplatin and occasionally carboplatin (150). The mechanism is poorly understood, and symptoms can be difficult to control with currently available medications, prompting the use of extended steroid administration, cannabinoids, or repeated dosing with 5-HT₃ receptor antagonists.

Anticipatory nausea and vomiting can become a significant problem during repeated cycles of chemotherapy, as patients associate environmental cues (such as odor, carpeting, or paint colors) with nausea. In addition to behavioral modification, it can sometimes be modulated by pretreatment with antiemetics and amnesic drugs, such as benzodiazepines, administered orally at home prior to arriving at the treatment center. Lorazepam (0.05 mg/kg) can also be given by slow intravenous push 1 hour before therapy, with doses being continued as needed every 4 hours for up to 6 doses (151). Unfortunately, this particular schedule produces significant sedation and can be used only in hospitalized patients or outpatients with independent transportation.

Diarrhea, oral stomatitis, esophagitis, and gastroenteritis are also potential problems. Patients with significant oral or esophagogastric symptoms may have symptoms managed with oral viscous lidocaine (2%), other topical anesthetics, or parenteral narcotics in severe cases. Randomized controlled trials

following 5-fluorouracil-based chemotherapy or radiation have failed to document any clinical improvement with sucralfate, which can bind to ulcerated mucosa (152,153). However, randomized placebo-controlled trials have demonstrated that multiple intravenous doses of recombinant keratinocyte growth factor (palifermin) before and after treatment can reduce the incidence and severity of chemotherapy-induced oral stomatitis associated with bolus 5-fluorouracil (154), high-dose chemotherapy, or concurrent chemoradiation (155,156). In general, dose-limiting mucosal injury is uncommon with platinum-based combinations, taxanes, and other single agents used in the treatment of gynecologic cancer. While many patients might develop some degree of diarrhea in the setting of concurrent pelvic chemoradiation, palifermin has not been specifically evaluated in that setting.

In refractory cases, patients should be screened for secondary infectious complications, such as candidiasis and herpes simplex. Following treatment with irinotecan, noninfectious secretory diarrhea is a well-recognized dose-limiting toxicity associated with local exposure to the active metabolite SN-38 and is generally managed with prophylactic antimotility agents and intravenous hydration, with utilization of octreotide in severe cases. Diarrhea can also result from diffuse mucosal injury following administration of doxorubicin (including PEG-liposomal doxorubicin), 5-fluorouracil, methotrexate, and other agents. In the setting of recent surgery and chemotherapy, patients are also at increased risk for infectious diarrhea, and screening for *Clostridium difficile* is appropriate.

Alopecia

Scalp alopecia is one of the most emotionally taxing side effects of chemotherapy. Aside from long-lasting alopecia that follows cranial irradiation, it is almost always reversible, but it can be a major deterrent to successful chemotherapy. Total scalp alopecia is particularly common with drugs like doxorubicin and paclitaxel, and there is generally some degree of partial alopecia with cisplatin, carboplatin, cyclophosphamide, docetaxel, Vinca alkaloids, and 5-fluorouracil. In a minority of cases, patients treated with paclitaxel will also experience loss of eyelashes, eyebrows, and other body hair, which can be particularly distressing. A variety of physical techniques have been devised to minimize alopecia, including scalp tourniquets and ice caps designed to decrease scalp blood flow. Although partially effective, they are rarely successful with extended chemotherapy.

Skin Toxicity

Skin toxicities that occur during chemotherapy include allergic or hypersensitivity reactions (HSR), skin hyperpigmentation, photosensitivity, radiation recall reactions, nail abnormalities, folliculitis, palmar-plantar erythrodysesthesia (PPE, hand-foot syndrome), and local extravasation necrosis. Many of these are drug specific and self-limited, but occasionally they may be dose limiting.

PPE is a reversible but painful erythema, scaling, swelling, or ulceration involving the hands and feet. This occurs more often with chronic oral or intravenous medications, weekly treatment regimens, and formulations that increase drug circulation time, such as prolonged oral etoposide, weekly and continuous-infusion 5-fluorouracil, capecitabine, and PEG-liposomal doxorubicin, where it has emerged as a major dose-limiting toxicity (157).

Extravasation necrosis is a serious complication seen after tissue infiltration of vesicant drugs such as doxorubicin, dactinomycin, mitomycin C, and vincristine (158). These drugs should always be administered through a freely flowing intravenous line with careful monitoring. Caution is also required during

utilization of central venous ports, as malfunctions in the needle, hub, or tubing can be associated with gradual extravasation that will not be apparent for several hours (159). Small series have reported a limited experience with local infiltration or topical application of steroids, *n*-acetylcysteine, dimethyl sulfoxide (DMSO), and hyaluronidase, with variable results, and recommendations are imprecise. However, single or multiple intravenous doses of dexrazoxane, a topoisomerase II catalytic inhibitor, appear to offer specific protection against injury from anthracyclines, including doxorubicin and daunorubicin (160,161). Skin necrosis from some extravasations may eventually require surgical debridement and skin grafting.

Neurotoxicity

Peripheral neuropathy is the most common neurotoxicity encountered in gynecologic oncology and is a particular risk with administration of cisplatin, paclitaxel, docetaxel, nanoparticle albumin-bound (NAB) paclitaxel, epothilones, Vinca alkaloids, and hexamethylmelamine (162,163). Although less common with carboplatin than cisplatin, neuropathy can still occur, particularly in combination with paclitaxel. Peripheral neuropathy generally begins with symptoms of paresthesia accompanied by loss of vibratory and position sense in longer nerves associated with the feet and hands. It then progresses to functional impairment, with gait unsteadiness and loss of fine motor coordination, such as trouble buttoning clothes and writing. This is closely followed by loss of deep tendon reflexes and eventual development of motor weakness. With paclitaxel and other nonplatinum agents, this is almost always reversible but may require several months posttherapy for substantial improvement. In more severe cases, accompanied by neuronal injury or demyelination, recovery may require active neuronal regeneration over an extended period of time, and symptoms may persist for the lifetime of the patient.

In current clinical practice, neurotoxicity from widely utilized microtubule-stabilizing agents is predominant (164,165). The frequency of moderate to severe toxicity is more common with paclitaxel, compared to docetaxel or epothilones. Risk appears related to peak levels associated with individual doses, as well as cumulative doses over multiple cycles, which is further complicated by alternative schedules and newer drug formulations. For example, although the risk associated with NAB-paclitaxel on the FDA-approved 3-week schedule is at least as high as paclitaxel (166), the risk is reduced with NAB-paclitaxel administered on a weekly schedule, even with higher cumulative doses. In addition, as the primary means of assessment is clinical, reported frequencies vary widely in clinical trials, reflecting variability in documenting history, and subjective and objective findings.

If related to cisplatin, neuropathy can continue to progress after therapy has been discontinued owing to ongoing axonal demyelination and loss, with long-term persistence of symptoms. Cisplatin has also been associated with permanent ototoxicity and, at higher doses, with loss of color vision (167) and autonomic neuropathy. Oxaliplatin can produce a long-term peripheral neuropathy similar to cisplatin (168), but it is also associated with transient acute reactions, including paresthesia and cold-sensitive laryngeal dysesthesia (169), which may reflect blockade of membrane ion channels (170). Infusions of calcium and magnesium have been used to ameliorate acute oxaliplatin reactions (171), but the potential risk of interfering with clinical response has not been resolved.

Although some patients report transient distal paresthesia after a single dose of paclitaxel, the onset of persistent neuropathy is generally more gradual. Neuropathy can become clinically apparent after 2 to 3 courses of therapy, with mild symptoms that resolve between cycles. Careful questioning and examination may reveal subtle findings at an earlier stage, and functional assessments have been developed that demonstrate good concordance

with actual neuropathy (172). Patients with underlying neurologic problems, such as diabetes, alcoholism, or carpal tunnel syndrome, are particularly susceptible, and substitution of docetaxel for paclitaxel can be a useful strategy in some situations. All patients who receive potentially neurotoxic therapy, especially cisplatin and paclitaxel, should be routinely queried regarding proprioception and fine motor tasks and examined for loss of vibratory sense, high-frequency hearing, and deep tendon reflexes.

In view of the frequency of neurotoxicity and the impact on daily life, there has been interest in agents that might prevent nerve damage, encourage recovery, or ameliorate symptoms (173). Amifostine was reported to reduce the frequency and severity of platinum-mediated neuropathy. However, a non-randomized study in patients receiving cisplatin and paclitaxel in combination with amifostine failed to achieve a targeted reduction in the incidence of neuropathy (174). In addition, widespread substitution of carboplatin for cisplatin has reduced, but not eliminated, the overall risk. Small studies with glutamine, vitamin E, and other agents have been inconclusive, and there are no agents that can be recommended for prevention of neuropathy in routine practice. Clinical management of painful paresthesia has been reported with amitriptyline and gabapentin (175), prompting the empiric use of similar agents for relief of symptoms.

Other neurotoxicities include acute and chronic encephalopathies, usually associated with intrathecal chemotherapy, acute cerebellar syndromes, autonomic dysfunction, inappropriate secretion of antidiuretic hormone (SIADH), and cranial nerve paresis. Of particular relevance to the gynecologic cancer population, an acute reversible metabolic encephalopathy has been well-described in association with ifosfamide and attributed to the toxic metabolite chloroacetaldehyde. Of note, this syndrome can potentially be prevented by infusion of methylene blue (176), which may act through inhibition of monoamine oxidase activity with reduced chloroacetaldehyde formation in the liver.

Genitourinary Toxicity

Renal toxicity is a well-recognized side effect of cisplatin, with implication of specific local metabolites, even though only a small fraction of cisplatin is cleared by renal excretion. In contrast, carboplatin undergoes extensive renal clearance with little risk of toxicity. Indeed, with increased substitution of carboplatin for cisplatin, and with a reduction in overall cisplatin dose intensity, there has been a decline in clinical familiarity with cisplatin-mediated nephrotoxicity. However, the expanded utilization of concurrent cisplatin and pelvic radiation for management of early-stage cervical cancer has renewed awareness of this potential problem, particularly as commonly utilized weekly dosing can exceed 100 mg/m² over a 3-week period. Careful attention to hydration status and saline-driven urinary output before, during, and immediately after therapy is required to reduce the risk associated with this serious complication (177).

Another troublesome side effect is hemorrhagic cystitis, which can be seen with cyclophosphamide or ifosfamide, attributed to the metabolite acrolein. With moderate-dose cyclophosphamide, this complication can be prevented by maintaining high urinary output, which reduces overall urothelial exposure to the toxic metabolites. However, patients receiving combination regimens often have reduced oral intake postchemotherapy, and selected patients receiving cyclophosphamide might benefit from supplemental intravenous hydration. The risk of cystitis is essentially 100% with ifosfamide, even with aggressive hydration, but this can be prevented with simultaneous administration of mesna, which binds and neutralizes acrolein in the urine (178).

Hypersensitivity Reactions

Increased utilization of paclitaxel, a natural product with poor solubility, has focused attention on the risk of HSR. For intravenous administration, paclitaxel is formulated in Cremophor-EL, a mixture of polyoxyethylated castor oil and dehydrated alcohol, which has been associated with mast cell degranulation and clinical HSR. Over 80% of reactions occur within minutes during either the first or second cycle of drug administration and can usually be managed with prophylactic medication (corticosteroids, histamine H₁/H₂ blockade) followed by rechallenge beginning at a lower rate of infusion (179,180). Similar reactions have been reported with docetaxel and PEG-liposomal doxorubicin, but with lower frequency in the absence of Cremophor-EL. Emerging data with NAB-paclitaxel indicate a marked reduction in the risk of HSR, further emphasizing the role of formulation, vehicle, and carriers.

With improved survival and an increased utilization of second-line therapy, patients can also experience more traditional allergic reactions to selected chemotherapy agents. Carboplatin, an organoplatinum compound, has emerged as a major source of late allergic reactions. These occur most often during the second cycle of a second course of therapy, suggesting a process of antigen recall and priming of the immune response (181). Patients receiving a second course of carboplatin-based therapy should be closely monitored for early signs of hypersensitivity to avoid more serious reactions. Unlike the situation with paclitaxel, carboplatin reactions are not readily prevented or circumvented with prophylactic medication, although inpatient (182) and outpatient strategies for desensitization have been reported (183) and successfully utilized for responding patients. It is important to note that the desensitization routine does not eliminate the allergic process and must generally be repeated with each cycle of treatment. Of interest, the combination of carboplatin with PEG-liposomal doxorubicin has a much lower incidence of carboplatin allergy, compared to a combination of carboplatin and paclitaxel or single-agent carboplatin, and might be preferred in the management of recurrent disease (184).

Other Significant Toxicities

A comprehensive discussion of all potential toxicities for currently available chemotherapeutic agents is beyond the scope of this chapter, and additional information is available throughout the text. Nevertheless, a variety of other important toxicities are occasionally encountered in regimens commonly used in gynecologic oncology. These include cardiac toxicity from cumulative doxorubicin exposure, radiation recall vasculitis from doxorubicin, pulmonary fibrosis from bleomycin, gonadal dysfunction in premenopausal women from alkylating agents, and secondary acute leukemia from the chronic administration of alkylating agents, particularly melphalan, in ovarian cancer.

DEVELOPMENTAL CHEMOTHERAPY

Background

The identification, evaluation, and regulatory approval of effective drugs for cancer treatment is a long, complicated, and expensive process. Of note, it has been argued that the expanded availability of only 17 existing generic chemotherapeutic agents would substantially improve worldwide mortality from cancer (185). However, most cases of advanced disease remain incurable with current treatments. Promising candidates are identified and prioritized through preclinical screening, utilizing derivatives of previously defined active agents or established drug classes or

new compounds engineered to interact with a specific target. In addition, there continues to be broad screening of natural products isolated from terrestrial and marine sources (186). Some evidence of antitumor activity during screening must be demonstrated before clinical trials are undertaken. Thus far, all useful antitumor agents have demonstrated antitumor activity using *in vitro* or *in vivo* screening systems.

These traditional approaches are being increasingly challenged by the large number of new genes and potential targets identified through molecular biology, genomics, and proteomics. Principles of genomic libraries, solid-phase organic synthesis, and combinatorial chemical library generation have been adopted by the pharmaceutical industry to promote high-throughput screening. As new targets are identified, a large number of related compounds can be created, beginning with lead natural products or known reagents, and then screened for improved target binding and/or inhibition of target function. Substantial bioinformatics resources are required to manage and analyze the large amount of data generated from these processes, but the accumulation of gene expression and proteomic data can facilitate “pre-discovery” modeling of potential targets and reagents prior to making decisions about actual development. To some extent, these processes have evolved in parallel, as it is clear that agents generated from a library or a database will still require some form of biologic validation prior to entering complex and expensive clinical studies.

After antitumor activity has been identified, the new agent must be formulated for human use and produced in sufficient quantities to support clinical trials. This is never a trivial achievement, as was evident from the natural supply limitations and formulation problems encountered in early trials with paclitaxel (187) and the camptothecins (188). Clinical-grade material is then subjected to detailed preclinical toxicology tests in animals. These toxicology trials are done in several animal species and may explore different schedules of drug administration to provide a basis for clinical development. As such, they are time consuming, complex, and expensive.

After all of the steps of preclinical testing are completed, new agents can enter clinical evaluation. As such, clinical trials are the primary means utilized to evaluate new agents in a systematic manner. All physicians and patients are urged to consider participation in clinical trials, which are available for almost all diagnoses and treatment circumstances. Sponsors of clinical trials include the NCI in collaboration with individual institutions and national groups, such as the GOG, as well as the pharmaceutical industry and individual institutions.

Clinical Trials

Detailed rationale and methodology for clinical trials design has been covered in other sections. This material is provided to highlight key concepts related to investigational drug development.

Phase 1 Trials

Phase 1 trials are typically first-in-human studies for new compounds and employ a dose- and/or schedule-escalating design to determine the dose-limiting toxicity (DLT), maximally tolerated dose (MTD), and pharmacokinetic parameters applicable to each regimen. In the most common model, accrual is suspended when more than one DLT event occurs within a dose level (2 of 6 patients), as this would generally exceed predefined limits for the MTD. Modifications of the standard dose-escalation schema have been developed to enroll fewer patients at lower dose levels with greater dose increments between successive dose levels in the absence of toxicity. As the MTD is approached, the dose level increments are reduced and accrual can be expanded. These newer methods aim to minimize the number of patients

treated at very low (nonefficacious and nontoxic) doses, while providing greater precision for estimating the MTD and DLT at higher doses.

With the shift from conventional cytotoxic agents to molecular-targeted agents, the traditional phase 1 paradigm needs to be reexamined. Many agents, such as human monoclonal antibodies, may not demonstrate traditional dose-limiting or dose-related toxicities, and phase 1 studies can reach their highest predetermined dose level without achieving DLT or defining a traditional MTD. In addition, these agents are frequently intended for chronic administration, and cumulative toxicity over multiple cycles is perhaps more relevant than acute toxicity during the first cycle. Finally, with an identified biologic target, it is also important to consider the optimal biologic dose that achieves a desired level of receptor blockade or signal transduction inhibition. With these considerations, it is apparent that a modified phase 1 design utilizing expanded cohorts treated for multiple cycles, with laboratory-based correlates, would provide better data to guide large randomized trials.

Tumor response is not a primary endpoint within a phase 1 trial, which will typically include patients representing a variety of primary tumor types with multiple prior therapies. Some phase 1 studies have included an expanded cohort to confirm safety and targeting, or an embedded phase 2 component to estimate clinical activity. These integrated strategies conserve patient resources while accelerating the overall development process, but with some risk of missing smaller treatment effects.

Phase 1 studies can also serve to evaluate new combinations that build on standardized chemotherapy regimens to establish feasibility and tolerability of the proposed regimen before embarking on larger trials. In certain situations, such as epithelial ovarian cancer, phase 1 trials may enroll newly diagnosed patients without prior therapy, as the experimental combinations generally incorporate other known active agents.

Phase 2 Trials

After the recommended dose and schedule have been defined, the regimen can receive focused evaluation in patients with a specific cancer diagnosis, usually in the setting of measurable disease after 1 (or 2) prior chemotherapy regimens. Phase 2 trials are designed and powered based on a surrogate endpoint that is thought to reflect potential clinical benefit, such as response rate, disease stabilization rate, biochemical (tumor marker) response rate, or the proportion of patients alive and progression-free at a specific time interval. In general, each phase 2 trial tests a single hypothesis, to determine if the new agent or regimen crosses a threshold based on historical data in the same patient population with an appropriate degree of power (type II or β error) and precision (type I or α error). Through this process, new agents are “selected” for further development or rejected. In order to conserve patient resources and minimize the number of patients who might receive ineffective therapy, most phase 2 studies utilize a multi-stage accrual design with early-stopping parameters, as proposed by Gehan (189) and modified by Simon (190).

This strategy was developed to efficiently screen conventional cytotoxic agents, one at a time, without direct comparisons between agents. It has obvious limitations when applied to targeted molecular agents, which may not have the same potential to elicit a measurable tumor response, or may be designed to work in conjunction with conventional therapy. As such, there is a risk that modest but clinically important treatment effects could be missed.

Traditional phase 2 trials utilize a single arm without randomization. However, there are circumstances where randomization is appropriate (191–193). Randomized phase 2 trials allocate patients among 2 or more treatment arms to minimize potential differences in prognostic factors or other variables.

Each arm is then independently tested against the same historical threshold value. Using this approach, one or both arms can be selected for further clinical development. Such randomized trials are generally underpowered for direct comparison of response rate and survival between each arm, owing to the limited number of patients.

In view of the number of new agents that merit evaluation, it would be appealing to have a more efficient paradigm that could incorporate combinations (with a reference arm) and offer the ability to compare and select among agents within the same general class. In practical terms, this has proven difficult, due to the need to involve multiple sponsors with different investigational agents. When early-phase data appear interesting but might not support a fully powered phase 3 trial, there have been randomized designs that incorporate an embedded phase 2 component to confirm disease-specific activity and feasibility prior to enabling full phase 3 accrual.

Phase 3 Trials

If a promising regimen is identified for further testing, it then moves toward a phase 3 randomized trial, in which it is directly compared with an existing standard regimen in a particular clinical setting, as defined by the type of cancer, stage of disease, and prior therapy. The size and duration of the trial depends on the primary endpoint (progression-free survival, overall survival, or quality-adjusted survival), anticipated effect size, and the power and precision of the statistical design. Generally, this is also a collaborative process, which combines scientific, clinical, and regulatory objectives.

Owing to the large number of uniformly staged and treated patients required for a phase 3 trial, such studies are best conducted through a national clinical trials organization with international collaboration. To minimize potential sources of bias, phase 3 trials frequently stratify patients into groups according to key prognostic variables prior to randomization, such as stage or extent of residual disease. This can expand the opportunity for preplanned post hoc analysis and contribute to the overall value of the study. Verification of patient diagnosis, stage of disease, eligibility, treatment delivered, and tumor response can further improve the reliability of reported results. Eligibility criteria and treatment flexibility represent a balance between scientific rigor, real-world clinical objectives, and ability to generalize findings.

The traditional phase 3 endpoint of overall survival has been challenged by an increasing number of available treatment options for management of recurrent disease, and the vast majority of well-planned trials fail to achieve a survival advantage. This has prompted greater consideration of progression-free survival as the preferred primary endpoint, as the timing of progression is not altered by secondary treatments. However, progression-free survival is subject to observer and detection bias, requiring better control over posttreatment monitoring. Regulatory authorities have also questioned if progression-free survival may not always translate into clinical benefit, without some type of adjustment for quality of life or control of disease-related symptoms. In view of these uncertainties, most registration trials include sufficient accrual to evaluate both progression-free and overall survival.

With the push toward targeted therapy and individualized treatments, there has also been increased pressure from regulatory agencies to include companion diagnostics to predict the likelihood of response and to select appropriate patients. However, not all presumptive biomarkers will be validated, and it is sometimes more useful to include a wider variety of patients with tumor specimens that can be studied for multiple markers and pathways. In addition, if the patient population is too narrowly defined, it may be more difficult to randomize patients to a treatment arm that does not include access to a particular drug.

FDA Approval and Postmarketing Studies

Following a successful phase 3 trial or, preferably, a group of related trials, a sponsor can apply to FDA for marketing approval for a specific disease indication. This triggers a detailed review of data by the Oncology Drug Advisory Committee (ODAC), which then issues a recommendation to FDA, followed by formal review and a decision by FDA, which may grant approval or request additional data. In the United States, all commercial marketing requires FDA approval for at least one specific indication. The average time from initial drug discovery to application for an FDA-approved indication is 10 to 12 years, involving considerable expense and effort, as noted above. Supplemental phase 4 or postmarketing studies can be required by FDA as part of the approval process or be performed by the sponsor to evaluate alternative drug formulations or resolve questions regarding dose, schedule, or toxicity. In addition, phase 4 studies may involve substitution of the new agent in combination chemotherapeutic regimens already established for the disease. These studies are not commonly employed in the development of new chemotherapeutic regimens, but can provide confirmatory evidence of safety and efficacy.

Development of Combination Regimens

With some notable exceptions, single agents are not sufficient to achieve prolonged survival or cure. Combinations of conventional cytotoxics can approach maximal cell kill by including drugs with minimal overlap of toxicities, such that antitumor effects can be summed but the toxicities dispersed. Combinations are also more likely to demonstrate activity against heterogeneous tumor populations, and effective combinations would prevent the emergence of drug resistance. However, in practice it may also encourage greater resistance among surviving cell fractions.

No direct evidence currently exists to indicate whether optimal combinations should utilize sequential single agents, doublets, or triplets. Utilization of single agents generally precludes any biologic interaction between the various components of a treatment regimen, but permits administration of each agent at the full active dose. The use of doublets generally permits higher doses of individual drugs, compared to a triplet regimen, but over a smaller number of cycles with each agent. Doublets have the potential advantage of sequentially introducing more than one regimen with a different mechanism of action and/or pattern of resistance, which has been postulated to prevent the emergence of drug resistance.

Development of combination chemotherapy has been guided by several principles (Table 13.11). However, much of the reported experience has been derived from empiric combinations

Table 13.11 Principles of Combination Chemotherapy

Each component should have

- Activity against the target tumor as a single agent
- A different mechanism of action and cellular target
- A biochemical basis for additive or synergistic effects in combination with at least one of the other agents
- No evidence of antagonistic interactions
- Distinct patterns of resistance to discourage the emergence of drug-resistant phenotypes

Optimal dose, schedule, and sequence of drug administration should be determined from preclinical data and early clinical trials to maximize tumor response and minimize host toxicity.

Minimal overlap of nonhematologic toxicity is desirable to safely maintain full therapeutic doses of each component over multiple cycles.

Table 13.12 Representative Agents for Development of Combination Regimens

Agent	Cellular Target	Mechanism of Action	Schedule-Dependent Effects	Patterns of Resistance	Interaction with Platinum
<i>Platinum</i>	DNA	DNA adduct formation	Generally independent of schedule	↑ GSH ↑ DNA repair ↑ Damage tolerance ↓ Accumulation	NA
<i>Paclitaxel</i>	β tubulin	↑ Tubulin aggregation	↑ Heme and mucosal toxicity with prolonged infusion ↑ Efficacy with weekly schedule	↑ MDR 1 (P 170) ↑ Tubulin- β 3 isoforms	↓ Platelet toxicity ↑ Neuropathy
<i>Topotecan</i>	Topoisomerase-I	Stabilize DNA-topoisomerase complex	↑ Efficacy with 5-day exposure Sequence-dependent toxicity	↓ Topoisomerase-I ↑ BCRP (ABCG2)	↑ Heme toxicity
<i>Gemcitabine</i>	Ribonucleotide reductase, DNA, nucleotide pool	↓ DNA synthesis ↓ Nucleotide pools Masked chain termination	Saturated uptake and phosphorylation with rapid infusion	↑ Ribonucleotide reductase	↑ Heme toxicity
<i>PEG-liposomal doxorubicin</i>	Topoisomerase-II	↓ DNA synthesis	Prolonged clearance (PEG formulation)	↑ MDR 1 (P 170)	↑ Heme toxicity

evaluated in conventional phase 1 dose-escalating trials. Bone marrow recovery usually proves to be the dominant factor in cycle timing, and in practice most combinations can be repeated every 3 to 4 weeks. Dose-dense strategies have also been developed using weekly or biweekly schedules.

Several combinations were evaluated in epithelial ovarian cancer, in an effort to improve on the results obtained with a standard combination of carboplatin and paclitaxel (Table 13.12). Each of the selected agents (topotecan, gemcitabine, and PEG-liposomal doxorubicin) had demonstrated independent single-agent activity against recurrent ovarian cancer, and could interfere with repair of platinum-DNA adducts, providing a clinical and scientific rationale for the combinations. However, based on completed phase 3 trials in approximately 12,000 women, none of the combinations achieved an improvement in clinical outcomes, providing additional support for a shift in developmental priorities toward molecular-targeted agents and other novel approaches (194).

Drug Interactions, Scheduling, and Sequence

Drugs should be used in their optimal dose and schedule. However, new combinations have the potential to alter the pharmacokinetics, bioavailability, toxicity, and efficacy of individual components based on substrate-dependent effects, such as a reduction in nucleotide pools or altered metabolism. Therefore, the optimal dose and schedule for individual agents within a combination might differ from their use as single agents.

As an illustration, the impact of sequence variations using cisplatin or carboplatin with either paclitaxel or topotecan has been explored in phase 1 clinical trials. Prior administration of cisplatin can delay subsequent clearance of paclitaxel when administered as a 24-hour infusion (195). The mechanism for this effect is unknown, but it is not attributable to platinum-mediated renal dysfunction. Instead, it has been postulated to occur following cisplatin-mediated inhibition of cytochrome P450 mixed-function oxidases that participate in paclitaxel metabolism. This enzymatic effect is not shared by carboplatin, and prior carboplatin exposure has not been demonstrated to interfere with clearance of paclitaxel. However, most combinations with carboplatin have utilized a shorter (3-hour) paclitaxel infusion, to minimize hematologic toxicity. Earlier preclinical models had demonstrated enhanced cytotoxicity when paclitaxel was administered prior to cisplatin and antagonism by the reverse sequence (196, 197). Thus, the schedule ultimately

adopted in clinical practice (paclitaxel followed by cisplatin) is both less toxic and potentially more efficacious, and this was empirically extended to carboplatin-based combinations. In part, this sequence was based on practical considerations related to the risk of acute paclitaxel HSR, which can require interruption of treatment, and it was more acceptable to administer the carboplatin after it was clear that the patient had already tolerated the paclitaxel.

A different pattern was observed with sequences of platinum and topotecan. Preclinical models have consistently favored the sequence of cisplatin followed by topotecan, which has been postulated to interfere with repair of platinum-mediated DNA damage. In a phase 1 clinical trial, treatment with cisplatin on day 1 was associated with increased bone marrow toxicity, compared with the reverse sequence (198). In this instance, the sequence recommended for further clinical evaluation was also more toxic, and the question of antitumor efficacy remains to be resolved. When combined with carboplatin, the risk of hematologic toxicity was further accentuated, and a similar sequence-dependent relationship was identified (199). Once again, higher doses of topotecan could be safely administered using the reverse sequence of drug administration (with carboplatin on day 3). Topotecan has also been evaluated in sequence with docetaxel (200), showing a reduction in docetaxel clearance associated with increased neutropenia when topotecan was administered prior to docetaxel, emphasizing that each new combination may require independent evaluation.

Even with a single drug, the schedule of administration can have a significant impact on host toxicity and potential efficacy (Table 13.13). Early studies with paclitaxel utilized an arbitrary 24-hour infusion, which was selected to reduce the risk of HSR. Preclinical data suggested that prolonged exposure (96 hours) might have greater efficacy. Owing to increased bone marrow and mucosal toxicity, the MTD was lowered, and the frequency of serious neuropathy was reduced. However, the 96-hour regimen was not demonstrated to have significant activity in patients with recurrent ovarian cancer (201). In addition, the efficacy of a 3-hour infusion was comparable to a 24-hour infusion in a phase 3 trial (202), reinforcing a clinical shift toward the convenient 3-hour schedule, which achieved a higher MTD, primarily due to a marked decrease in bone marrow toxicity, but with an increased incidence of neuropathy. This was followed by phase 1 evaluation of a weekly low-dose 1-hour infusion, which was almost devoid of serious toxicity, including a decreased incidence of alopecia, with maintenance of clinical efficacy (203). Thus, the optimal preclinical regimen (96-hour exposure)

Table 13.13A Impact of Paclitaxel Infusion Duration and Schedule on Toxicity and Efficacy

Paclitaxel Dose and Schedule			Dose-Limiting Toxicities				
Infusion Duration (hr)	Dose Interval (wk)	Single-Agent Unit Dose (mg/m ² /d)	Neutropenia	Mucositis	Alopecia	Neuropathy	Antitumor Efficacy
96	3–4	80–120	+++	++	+++	+	+++
24	3	135	++	0	+++	++	+++
3	3	175	+	0	+++	+++	+++
1	1	60–80	0	0	+	+	+++

was superseded in the clinical setting by an unexpected series of observations from empiric phase 1 trials, yielding decreased toxicity, improved convenience, and the potential for increased efficacy.

With topotecan, a different relationship was defined (Table 13.13b). Initial studies utilized an inconvenient daily infusion for 5 consecutive days, which was based on preclinical data suggesting that prolonged exposure would be more efficacious. This 5-day regimen achieved a 33% response rate in a GOG phase 2 trial in recurrent platinum-sensitive ovarian cancer with expected dose-limiting neutropenia and thrombocytopenia (204). This was followed by the evaluation of a single 24-hour infusion once every 3 weeks, achieving only a 7% response rate in a similar population (205). An attempt to define an intermediate 3-day regimen achieved only a 14% response rate (206).

Topotecan was also evaluated as a prolonged intravenous infusion for 21 days to maximize the duration of exposure (207). Although the study was conducted in a different patient population, the overall response rate (35%) was similar to the 5-day regimen, and once again there was equivalent hematologic toxicity without dose-limiting nonhematologic toxicity. When evaluated as a weekly treatment program, tolerability and acceptance were improved, but the overall efficacy was reduced (208, 209). In this situation, changes in drug schedule, over a wide range, were associated with substantial differences in efficacy, but without any change in the spectrum or severity of host toxicity, with the exception of reduced hematologic toxicity on the weekly schedule. Thus, each new agent needs to be independently evaluated in the appropriate clinical setting to select the optimal dose and schedule for cancer treatment.

Table 13.13B Impact of Topotecan Infusion Duration and Schedule on Toxicity and Efficacy

Topotecan Dose and Schedule			Dose-Limiting Toxicities				
Infusion Duration (days)	Dose Interval (wk)	Single-Agent Unit Dose (mg/m ² /d)	Neutropenia	Mucositis	Alopecia	Neuropathy	Antitumor Efficacy
21	4	0.40	+++	0	0	0	+++
5	3–4	1.25	+++	0	0	0	+++
3	3	2.00	+++	0	0	0	++
1	3	8.50	+++	0	0	0	+
1	1	1.75	++	0	0	0	–
1	1	4.00	+	0	0	0	+

Pharmacology and Therapeutics in Gynecologic Cancer

DAVID S. ALBERTS ■ HILARY CALVERT ■ MARIA LLURIA-PREVATT ■
PAUL SUGARBAKER ■ BRADLEY J. MONK

The determinants of effective cancer drug therapies include drug disposition, tumor kinetics, and drug resistance. These factors profoundly influence the cytotoxicity of each anticancer drug and must be considered in designing therapeutic regimens. These principles are discussed in Chapter 15. In this chapter, we elaborate on the basic and clinical pharmacology of cancer chemotherapeutic and biologic agents and provide a limited discussion of cytotoxic, molecularly targeted antiangiogenesis and modulating/supportive care drugs useful in the treatment of patients with gynecologic cancer.

DETERMINANTS OF EFFECTIVE DRUG THERAPIES

Drug Disposition Factors

The term *pharmacokinetics* describes the time course of drug disposition in body fluids and tissues through the use of mathematical models. These models use an equation or set of equations to describe the concentration-versus-time profile of a specific drug after administration into the body. The models are often illustrated by box diagrams, with each box or compartment corresponding to a region of the body, although the compartments may not represent real anatomic regions. A drug is considered to be uniformly distributed within a compartment if its concentration within tissues has reached homogeneity.

Pharmacokinetic models may be useful in predicting the plasma or tissue concentrations of drugs in the body after any one of several routes or methods of drug administration. The simplest model has one compartment into which the drug is assumed to be instantaneously introduced, and elimination occurs by one linear route. The disappearance of the drug from this compartment can be described by a straight line if plotted on semilogarithmic graph paper. As discussed by Tozer (1), no one-compartment pharmacokinetic model can be used to describe the disposition of commonly used anticancer drugs; nevertheless, the one-compartment pharmacokinetic model lends itself to an understanding of the concept of plasma half-life (i.e., $t_{1/2}$), which represents the time required for the concentration of a drug at any point on the plasma concentration · time elimination curve to achieve half its value. This constant may be applied repeatedly, so that, for instance, only 25% of the drug remains in 2 half-lives. The equation for plasma half-life that can be applied to any linear plasma concentration-time elimination curve is as follows: $t_{1/2} = 0.693/\text{slope of the linear elimination curve}$ (i.e., λ_z or rate constant for that part of the curve). Unfortunately, the determination of the terminal half-life of a drug is often poorly reproducible because it is highly

dependent on measuring multiple plasma levels, often at the limit of drug assay sensitivity.

Pharmacokinetic Models

The pharmacokinetics of virtually all anticancer drugs requires 2- or 3-compartment models for their mathematic description. These models are commonly referred to as biphasic or triphasic models (i.e., 2 or 3 phases observed on semilogarithmic plots). Conceptually, the one-compartment model relates to a drug that remains confined to the intravascular space after intravenous injection, and the 2- or 3-compartment model allows the pharmacokinetic description of anticancer drugs whose ultimate targets are beyond the intravascular space in tumor tissues.

Drug Clearance and AUC Concepts

Wisdom dictates using the simplest mathematical model that can provide the “best” fit of the actual plasma concentration time data using nonlinear least squares regression. After the mathematic model is selected, it is possible to generate the important pharmacokinetic parameters that describe the disposition of a specific anticancer drug within the body. Besides the determination of the terminal-phase plasma half-life (i.e., half-life related to the second or third phase of biphasic or triphasic plasma concentration time data), the area under the plasma disappearance curve ($AUC_{0-\infty}$) and total body plasma clearance (CL_T) are the most significant and clinically useful pharmacokinetic parameters. The relationship between AUC and clearance is simplified to: $\text{dose} = \text{clearance} \times \text{area}$.

Although the height of an anticancer drug’s peak plasma level ($C_{\max}$) generally correlates with peak dose and the degree of toxicity, the drug’s plasma AUC tends to correlate better with its ultimate antitumor activity and normal tissue side effects. For example, when identical doses of melphalan are administered first orally and then intravenously at a 1-month interval, because of its poor oral availability, the melphalan plasma AUC after the oral dose would be only one-third of that after the intravenous dose (Fig. 14.1). As would be anticipated, the equivalent intravenous dose of melphalan was associated with a two-fold to threefold deeper nadir in granulocytes and a greater than twofold increase in objective response rates in various cancer types (e.g., myeloma).

The plasma AUC (in $\text{mg/mL} \cdot \text{hour}$) can be estimated through the use of a pharmacokinetic model or measured directly by plotting the drug’s plasma concentrations against time on semilogarithmic graph paper. Then, it is possible to calculate the areas of successive trapezoids under the concentration vs. time

FIGURE 14.1. Plasma disappearance curves for intravenous and oral (tablets) melphalan (0.6 mg/kg) in a patient with ovarian cancer. The melphalan plasma AUC associated with the bolus oral dose was only one-third of that associated with the intravenous dose.

Source: Reprinted with permission from Alberts DS, Chang SY, Chen HS, et al. Oral melphalan kinetics. *Clin Pharmacol Ther.* 1979;26:737–745.

curve wherein the upper surface of the trapezoid is a line that connects 2 successive plasma concentration data points. By convention, when the plasma AUC is measured in this way, the terminal part of the AUC is calculated using a triangular area, rather than a trapezoid.

After the plasma AUC has been determined, it is possible to derive the anticancer drug's total body clearance rate based on the following formula: $CL_T = \text{dose (mg)}/\text{AUC (mg/mL} \cdot \text{hour)}$. The resulting CL_T is measured in units of milliliters or liters per minutes or hours, sometimes with normalization to the body surface area. The total body clearance of an anticancer drug depends on the drug's dose and plasma AUC and represents the rate at which the drug is eliminated from the entire body. The drug's total body clearance is made up of the combination of renal clearance (CL_R) plus nonrenal clearance (CL_{NR}). The renal clearance of a drug can be calculated by the following equation: $CL_R = Ae_c/\text{AUC}$, where Ae_c is the total amount of the unchanged drug that is excreted in the urine. For many drugs that are glomerularly filtered but not reabsorbed, renal clearance is proportional to creatinine clearance. In a patient with severe renal impairment, if nonrenal clearance is unaltered, the total body clearance of the drug is diminished significantly. This phenomenon is observed in patients with relatively severe renal impairment who receive drugs like methotrexate and carboplatin, both of which are eliminated mainly through renal excretion.

Volume of Distribution

The volume of distribution (Vd) of an anticancer drug is another important pharmacokinetic parameter that relates the drug plasma concentration (measured at the time of administration through

extrapolation of the terminal phase of the concentration-time curve to 0 time) to the total amount of drug in the body. Thus, Vd_{area} represents the volume of distribution of a drug in the terminal phase of its elimination from the body, and in its simplest form, $Vd = \text{amount of drug in the body} \div \text{plasma concentration}$. Since drug levels are typically measured only in the plasma compartment and not in tissues, most reported Vd values represent the "apparent" Vd of the drug in the plasma. Thus, these Vd values represent a theoretic plasma volume that would account for the drug's plasma levels after administration. The volume of distribution in the terminal phase can be derived using the following equation: $Vd_{area} = \text{dose}/\text{AUC slope } (\lambda_z)$, where λ_z is the rate constant in the terminal phase of a biphasic or triphasic elimination curve.

Linear and Nonlinear Kinetics

Most drugs exhibit linear pharmacokinetics, which in its simplest configuration means that the C_{max} and AUC are proportionate to the dose, and the $T_{1/2}$, Vd and clearance are constant; that is, they do not change with the dose. Linearity helps make predictions about the effects of changes in doses since the AUC (and the biological effects) of the drug should change in proportion to the dose. Drugs with nonlinear pharmacokinetics such as aspirin, ethanol, and phenytoin, have saturable elimination patterns. This means that small dose changes can disproportionately increase the AUC and the drug's biologic effects. Drugs with nonlinear pharmacokinetic patterns may therefore have longer $T_{1/2}$ s and much lower clearance values when the dose is increased.

As discussed by Collins and Dedrick (2), there are at least 2 explanations for nonlinear kinetics. First, nonlinearity may be caused by changes in drug excretion at high doses. For example, at extremely high doses of methotrexate (i.e., 7 to 8 g/m²), the drug load outstrips renal tubular secretion capacity. Second, nonlinearity may be observed for drugs that depend almost completely on elimination through a specific degradative enzyme system (e.g., antimetabolites). Drugs like cytarabine and 5-fluorouracil administered in high doses may overcome the capacity of their respective degradative enzymes with a resultant decrease in their total body clearance rates and an increase in plasma levels that are more than proportionate to their doses.

Intraperitoneal Drug Pharmacokinetics

Intraperitoneal drug administration has become an increasingly important therapeutic strategy in the management of patients with advanced ovarian cancer who have minimal residual intraperitoneal disease after primary or secondary exploratory laparotomies. Three large phase III trials in the Gynecologic Oncology Group (GOG) and the Southwest Oncology Group (GOG-104/SWOG-8501, GOG-114, and GOG-172) comparing various cisplatin-based combination chemotherapeutic regimens administered intravenously (IV) or intraperitoneally (IP) have documented significant survival advantages for the IP cisplatin treatment arms (3–5). In GOG-172, an IP regimen (IV paclitaxel on day 1, IP cisplatin on day 2, and IP paclitaxel on day 8) was associated with a 25% reduction in the risk of death compared to the intravenously administered regimen (IV paclitaxel plus cisplatin) ($p = 0.03$) (4). A meta-analysis of IP cisplatin-based randomized trials found that both overall and progression-free survival were significantly improved with IP regimens ($p = 0.0007$ and $p = 0.001$, respectively) (6).

Despite the superior activity of this IV paclitaxel/IP cisplatin-paclitaxel regimen evaluated in GOG-172, there was significantly

more hematologic, gastrointestinal, metabolic, and neurologic toxicity compared to intravenous paclitaxel and cisplatin (7); however, the dose of cisplatin on the IP arm was 33% higher than that of the IV arm. When combining the toxicity data across IP randomized trials, only acute gastrointestinal toxicity ($p = 0.01$) and fever ($p = 0.04$) are significantly higher among patients treated with IP therapy and ototoxicity was significantly higher among patients receiving IV treatment as compared to those receiving IP therapy ($p = 0.004$) (6). A study of patient quality of life within GOG-172 demonstrated that patient quality of life was significantly lower during IP treatment compared to IV therapy, but 1 year after treatment, the overall quality of life of patients receiving IP or IV therapy was equivalent (8). However, long-term neurotoxicity remained higher among patients treated with IP therapy. These short- and long-term effects should be balanced against the documented 16-month improvement in survival compared with IV cisplatin/paclitaxel ($p = 0.03$) (7). This increase in survival is similar to that achieved when IV cisplatin was initially added to primary combination chemotherapeutic regimens for the treatment of this disease (9).

The incremental increase in cisplatin efficacy associated with IP administration likely results from the delivery of approximately 20-fold greater concentrations of cisplatin into the IP space than is achievable with IV administration. Anticancer drugs with known activity against ovarian cancer that undergo slow clearance from the IP space into the systemic circulation without causing significant chemical peritonitis are the favored IP compounds. Clearly, paclitaxel falls into this category. IP administration of this large taxane molecule results in 1,000-fold greater concentration time products in the IP space than is achievable with IV administration (10). In contrast, cisplatin undergoes rapid clearance from the systemic circulation after administration via the IP route. Caution must be taken when considering other agents for research-based IP administration, as some cytotoxic agents have not demonstrated efficacy and have been associated with excessive toxicity when given IP (e.g., mitoxantrone, doxorubicin) (11–14).

As with the IV administration of anticancer drugs, the drug clearance rate from the IP space is the most useful pharmacokinetic parameter for comparing drugs that are administered by the IP route in the treatment of ovarian cancer. The peritoneal clearance rate can be calculated by dividing the drug dose by its IP concentration $\cdot$ time product, which must be measured with repeated IP fluid content sampling. Intraperitoneal drugs with slow clearance rates are favored because they result in prolonged exposure of the IP tumor bed to high concentrations of anticancer drug. It is also possible to assess the pharmacokinetic characteristics of drug doses by comparing their peak IP concentration with peak plasma concentration after IP dosing or comparing their IP concentration $\cdot$ time product (AUC_{IP}) with their plasma concentration $\cdot$ time products (AUC_{IV}) after IP dosing. Virtually all commonly used drugs administered intraperitoneally in patients with ovarian cancer have peak or concentration $\cdot$ time product ratios of more than 20. In some cases, the peritoneal exposures can be much greater. For example, paclitaxel IP exposure with IP therapy is 300 to nearly 3,000 times greater than with IV treatment (15).

Except for drugs whose cytotoxicity depends on continuous exposure, such as cytarabine and methotrexate, drugs used by the IP route should be administered relatively rapidly in at least 2 L of peritoneal dialysate and remain within the peritoneal space without removal. For schedule-independent drugs, it is important to maintain high concentrations as long as possible within the IP space to improve efficacy. It is of considerable interest that as the IP dialysate volume decreases, a drug's IP clearance rate increases rapidly. Thus, large volumes of IP fluid increase the chances for uniform drug distribution throughout

the IP space and optimize the IP clearance rates. Generally, it is suggested to administer the IP drug dose in the first liter of peritoneal dialysate, followed by a second liter of dialysate to the point of mild abdominal discomfort.

Ultimately, the effectiveness of IP therapy depends on the inherent cytotoxic potency of the individual agent and its ability to penetrate from the outer surface to the inner core of IP tumors. The degree of tumor penetration depends on the molecular weight, charge, and chemical structure of the compound. There is an inverse relationship between molecular weight and tumor penetration. The higher the molecular weight of the anticancer drug, the lower the degree of tumor penetration. Indeed, one advantage of cisplatin over carboplatin as an IP agent is its lower molecular weight. Los and colleagues (16) demonstrated in IP ovarian cancer animal studies that it requires almost 10 times more IP carboplatin than cisplatin to achieve similar intratumoral concentrations; however, there is renewed interest to develop IP carboplatin plus IP and IV paclitaxel regimens to reduce the potential for cisplatin-paclitaxel-induced peripheral neuropathy (see Special Applications, in Carboplatin section below) (17).

PERIOPERATIVE CHEMOTHERAPY AS A PLANNED PART OF THE CYTOREDUCTIVE SURGICAL INTERVENTION FOR PERITONEAL METASTASES

Oncologists agree that a combination of meticulous cytoreductive surgery plus treatment with cancer chemotherapy is necessary for optimal treatment of gynecologic malignancies. The prevention and treatment of peritoneal metastases from ovarian cancer is the most obvious challenge for this combined treatment plan. Also, endometrial cancer frequently causes peritoneal metastases and has been considered for not only systemic but also local-regional (IP) chemotherapy administration. Uterine sarcoma is another gynecologic malignancy that may be significantly benefited. Finally, low malignant potential ovarian cancers that fail a surgery alone approach may progress with disease confined to the abdominal and pelvic surfaces. Cytoreductive surgery with perioperative chemotherapy is a treatment option for these patients.

The principles of cytoreductive surgery utilizing visceral resections and peritonectomy procedures have been well described in the gynecologic oncology and surgical oncology literature. Surgical cytoreduction is an essential part of optimal treatment. However, chemical cytoreduction with cancer chemotherapy employed as a planned part of the operative intervention presents a new dimension in an attempt to optimize the management of gynecologic malignancy (18). Hyperthermic perioperative chemotherapy (HIPEC) is used in the operating room as part of the surgical procedure. In addition, normothermic early postoperative IP chemotherapy (EPIC) is administered in the first few postoperative days. As surgeons have ascended the learning curve for this combination of extensive surgery combined with perioperative chemotherapy, the mortality rate has been reduced to 1% or less. Also, grade III and grade IV adverse events have been reduced to 20% (19). Most recent publications associate the morbidity and mortality with the extensive cytoreductive surgery and estimate the adverse outcomes from the perioperative chemotherapy to be unusual. Of course, knowledgeable management of both aspects of the combined treatment is an absolute requirement for success.

Hyperthermic Perioperative Chemotherapy

The drugs used with the surgical procedure are those whose maximal cytotoxic effect is completed with a 60- to 120-minute treatment in the operating room. These chemotherapy agents should be augmented by moderate heat of approximately 42°C, which is maintained in the whole abdomen through the use of a hyperthermia pump (20). The chemotherapy agents used through an IP route or through an IV route as a multiagent HIPEC regimen include the following drugs:

Mitomycin C

The greatest experience with HIPEC comes with the IP administration of mitomycin C (21). The drug is used at 15 to 30 mg/m², depending on the other chemotherapy agents used simultaneously and the patient's history of prior systemic chemotherapy. The AUC ratio of peritoneal fluid concentration times time to plasma concentration times time is approximately 25. Over 90 minutes, 67% of the drug is retained within the body compartment. Approximately 9% will be excreted in the urine, and 29% will be removed when the chemotherapy solution is removed from the abdominal and pelvic space after the 90-minute hyperthermic treatment. The drug is administered either by an open or closed technique. Data suggest that patients with extensive prior surgery and limited peritoneal space are best treated using a closed technique, which produces moderate IP pressure to expand the abdominopelvic space and maximize distribution of both heat and chemotherapy. Large visceral resections, such as total colectomy, will diminish the clearance of mitomycin C from the peritoneal space. With increasing peritonectomy, a small increase (approximately 15%) in clearance from the abdominopelvic space into the plasma has been reported. The abdominopelvic temperature (normothermic vs. hyperthermic) has little effect on the pharmacokinetics of IP mitomycin C (22).

Cisplatin

Cisplatin has been utilized for 3 decades through the IP route with and without heat. The AUC ratio of IP concentration times time compared to plasma concentration times time is approximately 8. Sometimes ultra-high doses of IP or intrapleural cisplatin (250 mg/m²) can be administered as HIPEC or hyperthermic thoraco-abdominal chemotherapy (HITAC) when an infusion of thiosulfate is used via the IV route (23,24). If thiosulfate is given prior to or concomitant with cisplatin, bleeding within the cavity treated by chemotherapy must not occur or the thiosulfate will neutralize cisplatin activity local-regionally. The drug is augmented by heat, with a thermal enhancement ratio estimated at 2.9 at 41.5°C (25). The penetration of cisplatin into tumor tissue has been well documented (26).

Doxorubicin

Doxorubicin has received a large amount of preclinical and clinical investigation when used with hyperthermia. The drug is compatible in solution with cisplatin and has been frequently used as a 2-drug regimen with hyperthermia in the abdominal and pelvic space. The AUC ratio of concentration times time in the peritoneal fluid compared to plasma concentration times time is approximately 150. The dose of doxorubicin is limited by its known sclerotic effects. The optimal dose for IP administration is 15 mg/m² in 1.5 L/m² of fluid. The clearance will decrease

with extensive visceral resection and will increase approximately 10% with extensive peritonectomy. After 90 minutes of abdominopelvic treatment, 88% of the drug has entered the body compartment and 12% will be removed with suctioning of the chemotherapy solution from the body cavity at the close of HIPEC treatment.

Melphalan

Melphalan is a candidate for HIPEC because of its marked thermal enhancement with moderate hyperthermia (25). The drug has been successfully used with limb perfusion for melanoma and sarcoma and with liver perfusion for ocular melanoma. Howell et al. established the dose of drug at 60 mg/m², with a slight dose reduction in patients who have had extensive prior chemotherapy treatments (27). The AUC ratio of peritoneal fluid concentration times time over plasma concentration times time is approximately 90, but can be quite variable. The tissue concentration in peritoneal surface tissue or in tumor is approximately 50% of the IP fluid concentration and 10 times the plasma concentration (28). Clinical trials to estimate durable response using HIPEC with melphalan have not been done, but phase I/II investigations suggest benefit with melphalan used as a single agent.

One caveat in administering this drug concerns its rapid degradation by hydrolysis after mixing in a large volume of carrier solution. The drug should be hand-delivered promptly to the operating room from the pharmacy and instilled into the peritoneal cavity without delay. The temperature of the hyperthermic chemotherapy solution should not exceed 42°C.

Gemcitabine

Pharmacokinetic studies suggest that gemcitabine may be one of the most appropriate drugs for HIPEC. Its AUC ratio of peritoneal fluid concentration times time to plasma concentration times time is approximately 500. Nevertheless, 90% of the drug was cleared into the body compartment by 90 minutes (29). The cytotoxicity of the drug is synergized by heat, but the timing for the hyperthermia is not clear. The optimal interval between intraperitoneal drug administration and heat application has not been determined. It is possible that delayed heat may result in optimal cytotoxicity because of the intracellular metabolism of the drug as a requirement for its cytotoxicity (29).

Oxaliplatin

The administration of oxaliplatin differs considerably from the hyperthermic IP administration of other drugs. It is usually administered as a short pulse of high-dose drug over approximately 30 minutes. The dose is usually 460 mg/m² at 42°C. The drug is rapidly absorbed from the peritoneal cavity. The AUC ratio of peritoneal fluid concentration times time to plasma concentration times time is approximately double that of cisplatin (30).

The drug is not administered as a single agent within the peritoneal space. The systemic circulation is primed with a bolus of 5-fluorouracil shortly before the IP administration of oxaliplatin. The combined IV administration of 5-fluorouracil and abdominopelvic administration of oxaliplatin with heated peritoneal surfaces is designed to target small cancer nodules on peritoneal surfaces. The 5-fluorouracil reaches the carcinomatous nodule via a capillary network. The hyperthermic oxaliplatin gains access to the tumor nodule by simple diffusion from the chemotherapy solution within the abdomen and pelvis.

Bidirectional Hyperthermic Perioperative Chemotherapy

Ifosfamide

Intravenous ifosfamide as part of a cancer treatment regimen for ovarian malignancy was pioneered by Zylberberg et al. (31). When used IV as a continuous infusion, the dose is usually 1,300 mg/m². Approximately 20% of this dose should be matched by Mesna, which is given 15 minutes before and 4 hours and 8 hours after the ifosfamide infusion. Ifosfamide is an unusual drug with an extremely high thermal enhancement ratio (25). This may be as high as 10. It is an ideal IV drug for the heat targeting to the warm peritoneal surfaces by HIPEC. High concentrations of the active agent for hydroxy-ifosfamide are found within the peritoneal space and have been documented to be present within tumor nodules on peritoneal surfaces (32). Toxicities from the use of ifosfamide in combination with hyperthermic IP chemotherapy have been observed to be minimal.

5-fluorouracil

Heated IP chemotherapy for gastrointestinal cancer has been augmented through the use of IV 5-fluorouracil (30). Oxaliplatin alone is ineffective for gastrointestinal cancer and produces the greatest cytotoxicity when used in combination with a full dose of 5-fluorouracil. Drugs augmented by 5-fluorouracil include cisplatin, oxaliplatin, mitomycin C, and irinotecan. Van der Speeten et al. showed that IV 5-fluorouracil given as a bolus with HIPEC maintained a higher IP level compared to the IV drug level over 90 minutes of drug sampling. The AUC ratio of peritoneal fluid to plasma was 2.3 (± 1.3). The AUC ratio of peritoneal fluid to tumor nodules was 9.9 (± 9.8). The AUC ratio of plasma to tumor nodules was 5.2 (± 4.7). By modulating the route and timing of administration of 5-fluorouracil, it becomes a pharmacologic advantageous molecule in patients with peritoneal metastases (33).

Early Postoperative Intraperitoneal Chemotherapy

Cancer chemotherapy administered in the early postoperative period into the abdomen and pelvis in a large volume of fluid may gain access to all peritoneal surfaces because no significant wound healing has occurred at this point in time. Adhesions between bowel loops should be separated at the time of cytoreductive surgery so that loculations within the abdominopelvic space do not occur (22). The drugs are used in the absence of hyperthermia. Distribution within the peritoneal space may be augmented by gravity distribution. This means that the patient turns from an extreme right lateral to left lateral position postoperatively in a repeated manner. The drugs selected for EPIC should have a high molecular weight to cause a long dwell time and should be cell cycle-specific, resulting in their maximal effect over 4 or 5 days.

Paclitaxel

From a pharmacologic perspective, paclitaxel may be the most promising drug for administration in a large volume of fluid into the abdominopelvic space. The AUC of peritoneal fluid concentration times time to plasma concentration times time is approximately 1,000 (34). Also, a remarkable penetration of drug up to 80 cell layers has been published (35). Because of the long retention of paclitaxel within the abdominopelvic space, use of high-molecular-weight carrier solutions has been suggested to increase drug exposure to peritoneal surfaces over

time without increased systemic toxicity. With hetastarch as a carrier solution, a larger total volume of chemotherapy solution is retained in the peritoneal space with its high concentration of paclitaxel. The longer the ascites fluid remains, the longer the drug has to reach its maximal effect within the abdominopelvic space (36). When combined with other chemotherapy agents, IP paclitaxel is associated with a marked prolongation of median survival in peritoneal mesothelioma (36).

Docetaxel

Another taxane that has promise as normothermic IP chemotherapy as a planned part of postoperative management is docetaxel. The drug is minimally enhanced by heat but is retained within the peritoneal space for up to 24 hours. The AUC ratio of peritoneal fluid concentration times time to plasma concentration times time is 550 (34). This drug has been successfully used as a neoadjuvant IP chemotherapy agent for patients with gastric cancer.

5-fluorouracil

Undoubtedly, one of the oldest and best studied IP agents for gastrointestinal cancer is 5-fluorouracil. Because of its complete metabolism within a single pass through the liver, it has been suggested that the drug may not only treat cancer cells on peritoneal surfaces but also cause beneficial effects within the liver. The drug used is 400 to 600 mg/m² in the early postoperative period in 1 L of 1.5% dextrose peritoneal dialysis solution. Use of the drug intravenously with HIPEC and then intraperitoneally with EPIC can increase the total dose of 5-fluorouracil to 2 g/m² over the perioperative treatment cycle. This may be the optimal dose of 5-fluorouracil to use in combination with other drugs, such as oxaliplatin, cisplatin, or mitomycin C. The drug has been used not only to treat peritoneal metastases but in an adjuvant setting to diminish the incidence of carcinomatosis in patients at high risk for disease progression on peritoneal surfaces (37).

Floxuridine

Floxuridine is a unique chemotherapy agent because of its complete metabolism within a single pass through the liver by uptake of the drug into the portal vein. In phase I/II trials, IP floxuridine and systemic fluorouracil were successfully used to treat patients at high risk for locoregional recurrence after the resection of colon cancer (38). No liver metastases and no peritoneal carcinomatosis occurred during this treatment. The drug has a large potential for prophylaxis of peritoneal and liver metastases in a wide variety of malignancies.

Pemetrexed

Pemetrexed is a large-molecular-weight antifolate chemotherapy agent that has great promise for management of gynecologic malignancy. It is approved for treatment of peritoneal mesothelioma and is used intraperitoneally in combination with IV cisplatin for that disease. Its use in the perioperative period has not been fully explored. The AUC concentration times time after IP administration is 40 times the AUC for IV concentration times time. The half-life of pemetrexed in peritoneal fluid is 2 hours, suggesting prolonged activity within the abdominal and pelvic space (39,40).

Summary

An important consideration for HIPEC and EPIC concerns the selection of cancer chemotherapy agents that may show drug synergy. The bidirectional treatment with HIPEC and the continuing treatment postoperatively with EPIC present an opportunity to eradicate the peritoneal surface component of

gastrointestinal malignancy from the natural history of the disease. As surgeons learn to modify their surgical procedures in order to ensure a safe cytoreductive procedure, more effective combinations of both IV and IP chemotherapy used as HIPEC and EPIC become promising clinical approaches.

CLINICAL PHARMACOLOGY OF ACTIVE DRUGS AGAINST GYNECOLOGIC CANCERS

We discuss below in alphabetical order the clinical pharmacology of cytotoxic, biologic/molecularly targeted and modulating/supportive care drugs with demonstrated activity against gynecologic cancers. We also include several U.S. Food and Drug Administration (FDA)-approved drugs for other indications that may prove active against gynecologic cancers.

Cytotoxic Agents

Albumin-bound Paclitaxel

Chemistry

Albumin-bound paclitaxel (Abraxane, ABI-007) is a protein-bound form of paclitaxel that measures approximately 130 nm. Each vial of albumin-bound paclitaxel contains 100 mg of paclitaxel and 900 mg of human albumin. The chemical name of paclitaxel is 5 β ,20-Epoxy-1,2 α ,4,7 β ,10 β ,13 α -hexahydroxytax-11-en-9-one 4,10-diacetate 2-benzoate 13-ester with (2R,3S)-N-benzoyl-3-phenylisoserine, and the empirical formula and molecular weight are C₄₇H₅₁NO₁₄ and 853.91, respectively. Albumin-bound paclitaxel is FDA approved for the treatment of breast cancer after failure of treatment for metastatic disease or recurrence within 6 months of adjuvant chemotherapy. Phase III trials have demonstrated superior efficacy to castor-oil-based paclitaxel and a more favorable toxicity profile (41). Clinical trials in gynecologic cancer (e.g., ovarian and cervical cancer) are ongoing. Please refer to the Paclitaxel section for details on the mechanism of action of this agent.

Drug Disposition

According to the Abraxane package insert, comparison studies showed that the clearance of albumin-bound paclitaxel (260 mg/m² over 30 minutes) was larger (43%) than that for the clearance of paclitaxel injection (175 mg/m² over 3 hours), and the volume of distribution of the albumin-bound form was 53% higher; however, there was no difference in the terminal half-life of the active agent.

Administration and Dosage

The recommended dosage of albumin-bound paclitaxel is 260 mg/m² IV over 30 minutes every 3 weeks. No premedication to prevent hypersensitivity reactions is needed. Albumin-bound paclitaxel should be carefully reconstituted according to the manufacturer instructions. Each mL of the reconstituted formulation will contain 5 mg/mL paclitaxel. The exact total dosing volume of 5 mg/mL for the patient should be calculated using the following formula: total dose (mg) ÷ 5 (mg/mL). Reconstituted agent should be used immediately, but can be refrigerated for up to 8 hours. If precipitates are observed, the solution should be discarded.

Side Effects and Toxicities

Neutropenia and sensory neuropathy are dose-dependent. In drug approval studies, grade 4 neutropenia occurred among approximately 9% of patients compared to 22% of patients

receiving 175 mg/m² paclitaxel. Infection (generally oral candidiasis and respiratory system events) occurred in approximately 23% of patients receiving albumin-bound paclitaxel. Anemia occurred among 33% of patients (severe anemia in 1% of cases). Severe cardiotoxicity occurred in approximately 3% of patients. Dyspnea (12%) and cough (6%) were also reported among patients receiving albumin-bound paclitaxel. Patients with neutrophil counts of less than 1,500 cells/mm³ should not receive albumin-bound paclitaxel, as it may lead to bone marrow suppression, which can result in infection.

Altretamine

Chemistry

Altretamine (hexamethylmelamine, Hexalen), a synthetic cytotoxic antineoplastic s-triazine derivative, is FDA approved for the treatment of persistent or recurrent ovarian cancer after first-line chemotherapy with cisplatin or other alkylating agents. The drug also exhibits antitumor activity against breast cancer, lymphomas, small-cell carcinoma of the lung, and endometrial and cervical cancer. The empiric formula of altretamine is C₉H₁₈N₆ (molecular weight = 210.28).

Mechanism of Action

The mechanism of action of altretamine is not completely elucidated. Although it bears structural similarity to and cross reactivity with triethylene-melamine, a classic alkylating agent, evidence demonstrating altretamine to be an alkylating agent is inconclusive. Altretamine does not consistently demonstrate cross-resistance with classic alkylating agents used in rodent tumors or in human cancer treatment, but its clinical antitumor spectrum resembles that of an alkylating agent. Altretamine is inactive against most common murine and human tumor cell lines *in vitro*. Ruddy and Connors (42,43) presented definitive evidence that metabolic activation of altretamine is necessary for its cytotoxic activity. It is extensively demethylated *in vivo* in the presence of liver enzymes, and these N-methylolmelamine derivatives are more cytotoxic than the parent compound (43). Additional studies have shown that the reactive methyl intermediates, formed during altretamine N-demethylations, covalently bind to tissue macromolecules, including DNA, and that the cytotoxicity against certain human solid tumor cells *in vitro* is dependent on the metabolic formation of the reactive intermediates or their direct addition to cell culture incubate (44).

Drug Disposition

Altretamine is practically insoluble in water and, therefore, it has only been administered orally in clinical studies, precluding absolute bioavailability studies. After administration of altretamine to laboratory animals by any route, urinary recovery of parent drug was very low (<1%), and urinary recovery of total dose or total radioactivity after administration of ¹⁴C-labeled drug was as high as 90%. Ames (44) determined that the bioavailability of the parent compound in rabbits after oral administration was 25% of that obtained after IV administration. Moreover, after giving the rabbits labeled altretamine by stomach tube, 85% of labeled drug equivalents was recovered in the urine. The high rate of recovery suggests efficient gastrointestinal absorption.

The urinary recovery and bioavailability data demonstrate that altretamine is well absorbed after oral administration and that the drug is extensively metabolized, regardless of route of administration. The low bioavailability of intact altretamine is due to first-pass metabolism rather than to poor absorption.

After oral administration in doses of 120 to 300 mg/m², peak plasma levels, measured by gas chromatographic assay, from 0.2 to 20.8 mg/L are reached between 0.5 and 3.0 hours.

The terminal-phase plasma half-life ranges from 4.7 to 10.2 hours (45). The interpatient variability of AUCs, ranging from 1.2 to 60.1 mg/L · h, is most likely due to the differences in the rate at which the drug is metabolized.

Administration and Dosage

The recommended dose for altretamine as a single agent for use in the palliative treatment of patients with ovarian cancer is 260 mg/m²/day, orally, for 14 to 21 consecutive days in a 28-day cycle (46). The total daily doses should be given as 4 divided oral doses after meals and at bedtime. Compliance to this regimen in a small group of patients with relapsed ovarian cancer was documented at greater than 95% (47). There is no pharmacokinetic information on this dosing regimen and the effect of food on altretamine bioavailability in humans. In combination regimens, altretamine is typically used at a dose of 150 mg/m²/day for 7 to 14 days of monthly cycles (48,49).

Altretamine should be temporarily discontinued for 14 days or longer and subsequently restarted with a 20% to 25% dose reduction for any of the following side effects: gastrointestinal intolerance unresponsive to symptomatic measures; leukocyte count less than 2,000/mm³ or granulocyte count less than 1,000/mm³; platelet count less than 75,000/mm³; or progressive neurotoxicity. If neurologic symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued.

Side Effects and Toxicities

Altretamine is administered at a dose of 260 mg/m² (single agent) or 150 mg/m² (in combination) on an intermittent schedule and is relatively well tolerated. Single-agent data for this drug are available for 1,014 patients (50). With high, continuous daily dosing, nausea and vomiting were the dose-limiting toxic effects, and a form of reversible peripheral neurotoxicity occurred occasionally. Myelosuppression was mild to moderate. Leukocyte and platelet counts usually recovered within 1 week of therapy discontinuation.

In a study of 395 patients with advanced ovarian cancer treated with altretamine-containing combination regimens with or without cisplatin, no additional effect of altretamine on the incidence or severity of neurotoxicity could be demonstrated (51). Peripheral neuropathy and central nervous system symptoms are more likely to occur in patients receiving continuous, high-dose daily altretamine administered on an intermittent schedule than in those receiving moderate doses. Neurologic toxicity reverses after the drug is discontinued. Pyridoxine should not be used concomitantly with altretamine to reduce neurotoxicity because clinical trials data suggest it may inhibit cytotoxic activity. Concurrent administration of altretamine and antidepressants of the monoamine oxidase (MAO) inhibitor class may cause severe orthostatic hypotension. Cimetidine, an inhibitor of microsomal drug metabolism, increased altretamine's half-life and toxicity in a rat model.

In 2 phase II studies of single-agent altretamine, at a dose of 260 mg/m² for 14 to 21 days of each monthly cycle, the most common toxicity was grade 2 to 3 nausea (23%) (52,53). In a consolidation therapy phase II trial, only 3 patients (4%) experienced any grade 4 toxicity: granulocytopenia (2 patients) and anxiety/depression (1 patient). The most common grade 3 toxicities were malaise, fatigue, or lethargy in 7 patients (7%) and nausea in 6 patients (6%). Aside from these, there were no other grade 3 or 4 toxicities in more than 5% of patients (53).

With continuous high-dose daily drug administration, nausea and vomiting of gradual onset occur frequently. Although in most instances these symptoms are controllable with antiemetics, the severity sometimes requires altretamine dose reduction or, rarely, discontinuation.

Data from 3 large clinical trials demonstrated that altretamine can be added to full therapeutic doses of cyclophosphamide,

doxorubicin, and cisplatin (CHAP) without evidence of increased hematologic toxicity (54–56). Leukopenia below 3,000 cells/mm³ occurred in less than 15% of the patients on a variety of intermittent- or continuous-dose altretamine regimens. Less than 1% had leukopenia below 1,000 cells/mm³. When given in high doses over a 21-day course, nadirs of leukocyte and platelet counts were reached by 3 to 4 weeks, and normal counts were observed by 6 weeks. With continuous administration, nadirs are reached in 6 to 8 weeks.

Bleomycin

Chemistry

Bleomycin (Blenoxane), an antineoplastic, is a mixture of complex glycopeptides originally isolated from a strain of the fungus *Streptomyces verticillaris*. The primary components are bleomycins A₂ and B₂. The family of bleomycin glycopeptides have a relatively high molecular weight and are quantitated in units of cytotoxic activity (i.e., roughly 1 U/mg of polypeptide protein). Bleomycin is used as palliative treatment in patients with advanced cervical (57) and vulvar cancers. Other clinical indications include squamous-cell carcinomas of the head and neck, lymphomas, and testicular carcinoma. The molecular formula of bleomycin A₂ is C₅₅H₈₄N₁₇O₂₁S₃ (molecular weight = 1,414), and the molecular formula of bleomycin B₂ is C₅₅H₈₄N₂₀O₂₁S₂ (molecular weight = 1,425).

Mechanism of Action

Although the exact mechanism of action is unknown, a key to its activity is the isolation of native compounds from *S. verticillaris* as coordinated Cu(II) complexes, which are inactive as anti-tumor agents. When complexed with ferrous iron, bleomycin becomes a potent oxidase, producing DNA strand breaks by oxygen free radicals. Its unique mechanism of action is schedule dependent and cell cycle dependent for the G₂ phase.

The oxygen radicals produced by the bleomycin-iron complex bound to DNA primarily cause single-strand breaks and to a lesser degree, double-strand breaks. There is a subsequent release of base propenals of all 4 DNA bases: guanine, thymine, adenine, and cytosine. These modified free bases result from cleavage of the deoxyribose sugar at the 3' to 4' bond. There is an apparent specificity for the release of thymine and for DNA binding at guanine-rich sequences in actively transcribed genes (58). The linker regions of DNA between nucleosomes comprise an important site for specific strand cleavage by bleomycin (59). Several mechanisms have been theorized to explain the development of resistance to bleomycin. Less important mechanisms appear to include DNA repair, membrane alterations, and decreased drug accumulation. The primary mechanism probably involves metabolic inactivation of bleomycin by a cytosolic hydrolase, which is in the cysteine proteinase family. The enzyme inactivates bleomycin by replacing a terminal amine with a hydroxyl group. The distribution of bleomycin hydrolase appears to explain some of the relative resistance and sensitivity to bleomycin in normal tissues. Normal tissues with high intrinsic hydrolase activities, such as the liver, spleen, intestine, and bone marrow, are not targets for bleomycin's toxic effects. In contrast, lung tissues and skin have low levels of hydrolase activity and are particularly susceptible to bleomycin-induced toxicity. However, there appears to be no direct correlation between hydrolase levels in tumor cells and bleomycin-induced cytotoxicity (59). The development of other methods of bleomycin metabolism by tumor cells may be responsible for the emergence of drug resistance (60).

Drug Disposition

Bleomycin is eliminated predominantly by urinary excretion. This accounts for 45% to 62% of a dose after 24 hours. In

the blood, the drug is rapidly cleared, and 2 phases of elimination are apparent. As a practical point, this means that greater than 95% of a dose has been completely eliminated by 24 hours (about 6 half-lives) (61). If administered by an intracavitary route, a large percentage of a bleomycin dose is absorbed, and the fractional systemic bioavailability is approximately 45% for intrapleural or intraperitoneal injections. The drug appears to efflux more slowly from the peritoneal cavity. This suggests that there is significantly greater local drug retention in the intraperitoneal space. This may explain some of the drug's unique efficacy by intracavitary administration (62,63). An increased exposure to drug in these local compartments is also reflected by the tenfold higher drug levels achieved with IP or intrapleural therapy than with equivalent IV dosing.

Renal insufficiency markedly alters bleomycin elimination (64,65). This effect becomes most pronounced in patients with creatinine clearance values less than 25 to 35 mL/min (64). In these patients, the volume of distribution is unaltered at about 20 L, but the half-life varies as the inverse exponent of creatinine clearance. Thus, significant bleomycin dose reductions are required in all patients with reduced renal function.

Dosage

Bleomycin (in combination with cisplatin and etoposide or vinblastine) is used most commonly by bolus IV administration at dosages of as high as 30 mg/week for up to 12 weeks in the treatment of patients with germ-cell tumors of ovary. These 30-mg doses often are associated with delayed febrile episodes that can be inhibited successfully with a morning dose of dexamethasone or prednisone.

Bleomycin remains to be used commonly by continuous IV infusion at dosages of 10 mg/m²/day for 4 consecutive days, with courses repeated every 4 weeks. This schedule has been proven to be successful in the treatment of women with metastatic cervical cancer. Total bleomycin doses should usually not exceed 400 mg to avoid serious pulmonary toxicity.

Bleomycin can also be administered by the intramuscular route in doses of 15 to 30 mg. Absorption appears to be complete, and because of its lack of vesicant activity, the intramuscular route has been proven to be extremely safe (66).

Side Effects and Toxicities

Bleomycin's dose-limiting side effect is pulmonary toxicity, which occurs in approximately 10% of treated patients and in rare instances can result in death. The likelihood of lung damage increases with advanced age, chest irradiation (67), hyperoxia during surgical anesthesia (68,69), renal insufficiency, and cumulative doses greater than 400 U. However, pulmonary toxicity can occur in younger patients following low cumulative doses. Bleomycin-induced lung damage presents as pneumonitis with dry cough, dyspnea, and rales and may progress within weeks to pulmonary fibrosis. Bleomycin should be discontinued at the first clinical signs of lung toxicity. Acute pneumonitis is often responsive to corticosteroid therapy; however, there is no effective therapy for the chronic pulmonary fibrosis that may result from bleomycin therapy (70).

Evidence from preclinical models of bleomycin-induced pulmonary thrombosis has documented that pretreatment with amifostine can abrogate this dose-limiting toxicity (71,72).

Bleomycin is nonmyelosuppressive (a factor that facilitates its use in combination chemotherapeutic regimens). Mucocutaneous toxicities, including mucositis, are the primary acute side effects of bleomycin. Manifestations of cutaneous reactions include hyperpigmentation, erythema, rash, striae, pruritus, thickening of the nail beds, and in rare instances, scleroderma (73). Fever, chills, and alopecia are common. Mild nausea, vomiting, and anorexia may also occur but are typically self-limiting.

Infrequent side effects include headache, pain at tumor site, and anaphylactoid reactions. An idiosyncratic reaction consisting primarily of mucositis and skin rash has also been reported (74).

Special Precautions

Bleomycin should be used with extreme caution in patients with significant renal impairment or compromised pulmonary function; frequent radiographs are recommended. Because up to 70% of a bleomycin dose is eliminated by renal excretion, the bleomycin dose should be reduced for individuals with severe renal insufficiency. Unfortunately, there are no prospectively evaluated dosing nomograms for bleomycin dose adjustment. An empiric dose-adjustment formula has been described (64). The percentage dose reductions that are indicated by applying this formula to a "normal" creatinine clearance (CrCl) of 120 mL/min and a fractional urinary drug excretion of 0.45 are as follows: CrCl > 35 mL/min, no dose reduction required; CrCl = 20 mL/min, 50% dose reduction; CrCl = 15 mL/min, 52% dose reduction; CrCl = 10 mL/min, 55% dose reduction; and CrCl = 5 mL/min, 60% dose reduction. This is only a general guide, and it has not been clinically validated in a prospective study or retrospective analysis. Patients over 65 years of age may be at increased risk of developing orthostatic hypotension, especially when the recommended rate of IV infusion is exceeded.

Drug Interactions

Nephrotoxic drugs may significantly reduce the rate of bleomycin clearance and thus increase toxicity. Yee and coworkers (75) observed markedly reduced bleomycin clearance in children who had received 6 courses of a regimen including cisplatin (cumulative dose 300 mg/m²). In another case report, fatal bleomycin pulmonary toxicity occurred in a patient with cisplatin-induced acute renal failure (76). Similar toxic interactions should be anticipated for combinations of bleomycin with other nephrotoxic drugs, such as aminoglycosides, amphotericin, or cyclosporine.

Special Applications

Because of its nonvesicant nature, bleomycin has been administered by a number of nonvascular routes, including intramuscular (66), subcutaneous (77), and, most significantly, intrapleural routes for the management of malignant effusions. When compared with tetracycline, intrapleurally administered bleomycin, 60 to 120 U, had greater therapeutic benefit for the management of malignant pleural effusions (62,63). When compared with tetracycline, intrapleurally administered bleomycin, 60 to 120 U, had greater therapeutic benefit as evidenced by a longer time to effusion recurrence (46 vs. 32 days, $p = 0.037$) and a lower 3-month effusion recurrence rate (30% vs. 53%, $p = 0.047$). Because toxicities were similar for both therapies, bleomycin was selected as the preferred intrapleurally administered therapy for malignant pleural effusions (62,63).

There is evidence that a cytosolic hydrolase in the cysteine protein family inactivates bleomycin by replacing a terminal amine with a hydroxyl group. The distribution of bleomycin hydrolase appears to explain some of the relative resistance and sensitivity to bleomycin in normal tissues. Normal tissues with high intrinsic hydrolase activities, such as the liver, spleen, intestine, and bone marrow, are not targets for bleomycin's toxic effects. In contrast, lung tissues and skin have low levels of hydrolase activity and are particularly susceptible to bleomycin-induced toxicity. However, there appears to be no direct correlation between hydrolase levels in tumor cells and bleomycin-induced cytotoxicity (59). The development of other methods of bleomycin metabolism by tumor cells may be responsible for the emergence of drug resistance (60).

Capecitabine

Chemistry

Capecitabine (Xeloda) is an orally administered antineoplastic agent. In patients with metastatic breast cancer, capecitabine in combination with docetaxel is indicated after failure of prior anthracycline-containing chemotherapy, and monotherapy is indicated for those who are resistant to paclitaxel and are resistant to anthracycline-containing chemotherapy (or further anthracycline-containing chemotherapy is not indicated). Capecitabine is a fluoropyrimidine carbamate prodrug form of 5'-deoxy-5-fluorouridine (5'-DFUR) that is enzymatically converted to 5-fluorouracil (5-FU) *in vivo*. Its chemical name is 5'-deoxy-5-fluoro-N-[(pentoxyl) carbonyl]-cytidine and its molecular weight is 359.35.

Mechanism of Action

Capecitabine itself is inactive, but after absorption in the gastrointestinal tract it is metabolized to 5-FU by 3 enzymes: carboxylesterase, which converts capecitabine to 5'-deoxy-5-fluorocytidine in the liver; to 5'-deoxy-5-fluorouridine by cytidine deaminase in the liver and tumor tissue; and thymidine phosphorylase, which in many cases is highly expressed in tumors, completes the final step of conversion to 5-FU. Theoretically, capecitabine therapy is likely to be most effective in patients with tumors that express high concentrations of thymidine phosphorylase (resulting in greater 5-FU being generated in the tumor) and low concentrations of dihydropyrimidine dehydrogenase (which rapidly breaks down 5-FU) (78). 5-FU acts as a false pyrimidine or antimetabolite ultimately to inhibit the formation of the DNA-specific nucleoside base thymidine. The metabolites of 5-FU, 5-fluoro-21-deoxyuridine-5'-monophosphate (FdUMP), and 5-fluorouridine triphosphate (FUTP) inhibit thymidylate synthase (TS) and are incorporated into cellular RNA (FUTP). DNA synthesis and function is inhibited by the incorporation of FdUMP into cellular DNA (79). A pharmacogenetic study of capecitabine in 105 consecutive patients has shown an increase in toxicity in patients homozygous for the TS 3RG allele and also that a patient with a DPD IVS14 + 1G>A mutation died from toxicity emphasizing the importance of polymorphisms in the metabolizing enzymes of this drug (80).

Drug Disposition

After oral administration, capecitabine reaches peak blood levels in about 1.5 hours, and peak 5-FU levels are reached at about 2 hours. Food reduces the rate and extent of absorption for both capecitabine and 5-FU. Plasma protein binding is not dose dependent and is less than 60% for capecitabine and its metabolites. Capecitabine (95.5% of administered dose) and its metabolites are excreted in urine. Capecitabine has no effect on the pharmacokinetics of docetaxel or vice versa. The precise pharmacokinetics of capecitabine have been difficult to establish, which is thought to be due to the large interindividual and intraindividual variation in expression of the enzyme dihydropyrimidine dehydrogenase (78).

Administration and Dosage

Capecitabine is available as 150- and 500-mg tablets for oral use. The recommended dose is 2,500 mg/m² daily to be administered as 2 doses: 1,250 mg/m² in the morning and 1,250 mg/m² in the evening for 2 weeks followed by a 1-week rest (21-day cycle). Because of the high rate of grade 2 or greater capecitabine-induced palmar-plantar erythrodysesthesia (PPE), recommendations have been made to reduce the starting dose to 2,000 mg/m² daily. It should be taken with water within 30 minutes after a meal. The same dosage of capecitabine should be used when combined

with docetaxel, which should be administered at 75 mg/m² as a 1-hour infusion on day 1 of the 21-day cycle. Premedication (per docetaxel labeling) should be started prior to docetaxel administration for patients receiving the combination therapy.

Side Effects and Toxicities

The only side effect that occurs more frequently with capecitabine than with IV 5-FU is PPE (15% to 20% of patients). The other more common side effects of capecitabine include diarrhea (40%) and nausea and vomiting (30% to 40%). Grade 3 hyperbilirubinemia occurred in 15.2% and grade 4 in 3.9% of patients in the clinical safety database of Xeloda. Of those patients experiencing grades 3 and 4 hyperbilirubinemia, many (64% and 71%, respectively) had liver metastases at baseline, and 57.5% and 35.5% had elevations in alkaline phosphatase or transaminases, respectively. Other less common side effects include myelosuppression (less frequent than with IV 5-FU), leukopenia, and cardiotoxicity. In general, capecitabine is relatively well tolerated.

Special Precautions

Because capecitabine is administered orally, patients should be informed about how to monitor their toxicity symptoms and be instructed to maintain the prescribed dosing regimen. Capecitabine has been shown to alter coagulation parameters in patients undergoing treatment concomitantly with coumarin-derivative anticoagulants (e.g., warfarin) (78). Therefore, patients taking oral coumarin-derivative anticoagulant therapy should be monitored regularly with regard to coagulation parameters (international normalized ratio or prothrombin time). Patients over the age of 80 years and those with mild to moderate liver dysfunction should also be closely monitored.

Carboplatin

Chemistry

Carboplatin (Paraplatin) is platinum-based agent that is approved by the Food and Drug Administration for the treatment of patients with advanced ovarian cancer of epithelial origin. It is also active against metastatic endometrial and cervical cancer. Carboplatin has a molecular formula of C₆H₁₂N₂O₄ Pt and a molecular weight of 371.25. Its chemical name is cis-diammine-(1,1-cyclobutanedicarboxylato) platinum(II). The water solubility of carboplatin (14 mg/mL) is approximately 10 times that of cisplatin.

Mechanism of Action

Carboplatin, like cisplatin, produces an equal number of predominantly interstrand DNA cross-links rather than DNA-protein cross links, causing equivalent lesions and biologic effects. The differences in potencies appear to be related to the aquation rate, which is significantly higher for cisplatin compared to carboplatin (81). It covalently binds to DNA with preferential binding to the N-7 position of guanine and adenine (79). Like cisplatin, carboplatin must first undergo sequential losses of the nonamine carboxylato ligands. Although this process proceeds readily with the loss of the chlorides in cisplatin, the rate of leaving or "opening" of the carboxylato moieties in carboplatin is much slower (82). The molar potency of carboplatin in creating DNA lesions and cytotoxicity was observed to be roughly 2% of cisplatin *in vitro* and 25% to 33% of cisplatin *in vivo* (83,84). A more striking difference is the markedly delayed onset of peak cross-linking for carboplatin compared with cisplatin. With carboplatin, maximal DNA cross-linking occurs 18 hours after exposure compared with 6 to 12 hours for cisplatin (84). In addition, carboplatin-induced DNA cross-links appear to

have a slower rate of resolution than cisplatin-induced cross-links. This slower onset and offset of carboplatin cross linking is believed to be a direct result of a slow rate of monofunctional adduct formation or a slower rate of conversion of monoadducts to cross-links.

Although the final DNA adducts formed by cisplatin and carboplatin are the same, there are large differences in the kinetics of their formation and the rate of conversion of mono- to di-adducts (85), which could impact the ability of various DNA repair enzymes to cause resistance. Further, cell membrane transport proteins are thought to be critical determinants of platinum drug sensitivity and resistance. It is known that cisplatin and carboplatin differ in their transport characteristics (86). Leblanc et al. (87) showed that substantial hepatic P450 induction occurred in rats following cisplatin treatment, but not following carboplatin treatment. Waxman et al. (88) showed that cisplatin induced GST Yc expression in the liver of rats, but carboplatin did not. These data may be significant because GSTs are thought to contribute to platinum resistance. Natarajan et al. (89) extended the latter observation by showing that S-containing nucleophiles (thiourea, glutathione, and human breast cancer MCF-7 cell cytoplasmic extracts) significantly decreased the formation of DNA platinum adducts from cisplatin, but significantly increased them from carboplatin. Despite the pharmacokinetic and mechanistic differences between carboplatin and cisplatin, phase III studies and meta-analyses of clinical studies reveal equivalent activity between carboplatin and cisplatin in all prognostic subgroups of ovarian cancer patients (90,91). However, meta-analysis is performed on pooled data. It is entirely plausible that subsets of ovarian cancers with differing genetic phenotypes will respond differently to cisplatin and carboplatin.

Harrap (92) described nuclear protein phosphorylation after treatment with both cisplatin and carboplatin. These events appear to correlate with cell killing (93). Carboplatin reacts with 2 sites on DNA to produce cross-links, as has been observed with cisplatin (94). The formation of DNA adducts results in the inhibition of DNA synthesis and function and inhibits transcription (79). These lesions involve a bifunctional platinum adduct to a single-strand DNA. This may produce transcriptional miscoding and an inhibition of DNA synthesis. It is possible that the cytotoxic effects of carboplatin are the result of binding to nuclear and cytoplasmic proteins. Carboplatin-induced cytotoxicity is not cell cycle phase specific, but it can be maximized by exposing cells in S phase to the drug.

Drug Disposition

The pharmacokinetics of carboplatin differs significantly from that of cisplatin. Table 14.1 shows that the plasma clearance of carboplatin is biphasic and slower than that of cisplatin, with a much higher percentage of drug being excreted in the urine. Unlike cisplatin, carboplatin binds to plasma proteins relatively slowly so that in the first 24 hours after administration there is a considerable concentration of the free drug in circulation. The major route of elimination of carboplatin is glomerular filtration and tubular secretion. There is little or no true metabolism of the drug. The carboxylate bonds in carboplatin are slowly hydrolyzed to yield transient aquated intermediates. These activated platinum species are believed to lead directly to irreversible adducts to DNA or protein. Overall, the rate of hydrolysis of carboplatin is significantly slower than that of cisplatin, leading to much slower reactivity with DNA (95). Because at least 65% of a carboplatin dose is excreted in the urine, significant dose adjustments are recommended for patients with creatinine clearance values less than 60 mL/min. However, since the widespread use of formula-based dosing (see below) these reductions are implicit in the use of the formula and need not be separately calculated.

Table 14.1 Carboplatin Pharmacokinetics

Cumulative 24-hr Urinary Excretion	65% (if Creatinine Clearance >60 mL/min)
<i>In vitro</i> half-life (H ₂ O)	~24 hr
Plasma half-life β phase (free drug)	180 min
Protein-bound drug	>5 days
Volume of distribution	16–20 L
Protein binding	30% (slow equilibration)

Carboplatin is widely distributed in body fluids and achieves good penetration into pleural effusions and ascites fluid (96,97). Pharmacokinetic studies in patients receiving continuous carboplatin infusions show that although total platinum levels increase over the course of the infusion, free or active platinum levels can decrease from 78% on day 1 to 38% on day 4 of a 4-day infusion.

Administration and Dosage

Carboplatin is usually administered as a brief infusion in a solution of 0.9% sodium chloride or 5% dextrose in water. The drug is typically diluted in 500 mL of fluid and infused IV over 15 to 30 minutes to 1 hour without further hydration (98,99). Carboplatin also has been administered as a continuous 24-hour IV infusion for 1, 4, or 5 days or as a continuous IV infusion for 21 days.

The Calvert equation is the most frequently used formula for carboplatin dosing as it requires minimal calculations, results in predictable levels of myelosuppression, and prevents underdosing or overdosing in patients with excellent or poor renal function, respectively (100). The Calvert formula appears below along with general guidelines for selecting the specific carboplatin AUC.

Carboplatin total dose (mg) = AUC(mg/mL · min) · [GFR(mL/min) + 25] AUC = 7 when carboplatin is used as a single agent in patients with good bone marrow reserve; 6 when carboplatin is used in combination regimens in patients with good bone marrow reserve or when used as a single agent in patients who have had prior moderate chemotherapy; and 4 when carboplatin is used as a single agent in patients with prior heavy chemotherapy exposure.

Glomerular filtration rate (GFR) can be determined by measuring creatinine clearance (i.e., [⁵¹Cr]-ethylenediamine-tetraacetic acid) for all patients or estimated creatinine clearance for patients who have had no prior cisplatin exposure or have not had cisplatin for at least 2 months prior to carboplatin dose determination.

For example, if the desired carboplatin AUC is 6 for a patient with an estimated creatinine clearance (CrCl) of 75 mL/min, the total carboplatin dose would equal 6 × (75 + 25), or 600 mg.

As noted above, the Calvert formula uses the following estimate of carboplatin clearance: Cl = GFR + 25. Although the method may be optimal (101), isotopic determination of the GFR as measured by [⁵¹Cr]-ethylenediamine-tetraacetic acid (⁵¹Cr-EDTA) is not available in many countries and the estimated creatinine clearance is often substituted for the GFR. A commonly used method for estimating creatinine clearance is the Cockcroft-Gault (CG) equation (102):

$$CrCl = \frac{(140 - Age) \times Wt \times (1 - 0.15 \times Sex)}{72 \times SCr \times 0.0113}$$

CrCl = Creatinine clearance; Age = Age in years; Sex = 1 if female, 0 if male; SCr = Serum Creatinine in mmol/L; Wt = Weight in kg.

Both the CG calculation of creatinine clearance and creatinine clearance based on a 24-hour urine collection result in a systematic underestimation of the carboplatin AUC by approximately 10% (103–105). This level of bias may be deemed acceptable in view of the clinical utility of substituting creatinine clearance for GFR. Significantly, the accuracy of the CG calculation depends on the method used for measuring creatinine. When the CG formula was derived, a colorimetric reaction was used that significantly overestimates the plasma level of creatinine. A more accurate measurement uses an enzymatic method (106). The use of a more accurate method combined with the CG formula leads to an unexpectedly high dose of carboplatin. Recently, creatinine measurements in the United States have been standardized using isotope dilution mass spectrometry, leading to potential overdosage in some trial protocols and a recommendation for a dose cap (107). The issue of using a creatinine-based estimate of the GFR has been approached by Wright et al. (106) where alternatives to the CG formula are proposed for use with differing creatinine assays.

The Calvert formula has been prospectively evaluated by Sorenson et al. (108) in 24 previously untreated ovarian cancer patients and was found to predict more accurately carboplatin exposure than calculation of dose based on body surface area. The AUC of carboplatin as calculated by the Calvert formula accurately predicted the level of myelosuppression as determined by the relative decrease in the platelet count (108).

Although formula-based dosing is normally used, the recommendation dosage for single-agent carboplatin in mg/m² in ovarian cancer patients with good bone marrow reserve, based on body surface area, is 360 mg/m² given IV every 4 weeks. Because renal excretion is the primary route of carboplatin elimination, the carboplatin dose must be reduced for patients with compromised kidney function. The drug manufacturer's package insert recommends carboplatin doses of 250 and 200 mg/m² for patients with creatinine clearances of 41 to 59 and 16 to 40 mL/min, respectively.

The most frequently used primary chemotherapeutic regimen for advanced ovarian cancer is a combination of paclitaxel (175 mg/m² by 3-hour IV infusion) followed by carboplatin (at a targeted AUC of 5 or 6 by 30- to 60-minute IV infusion) every 21 days (if blood counts are adequate) for 6 cycles (109).

Side Effects and Toxicities

Although the activity is comparable to cisplatin, carboplatin is better tolerated, as measured by toxicity [e.g., low incidence of alopecia (110)] and quality of life analysis (91). The usual dose-limiting toxicity of carboplatin is bone marrow suppression, particularly thrombocytopenia (111). Leukopenia and anemia also occur but are less severe.

The platelet nadir is achieved 2 to 3 weeks after an IV bolus injection, and recovery is generally complete 4 to 5 weeks after dosing. However, patients with poor bone marrow reserve from previous chemotherapy or radiation therapy can have more profound thrombocytopenia and leukopenia with carboplatin treatment. Cell depletion may persist for several weeks after dosing.

Nausea and vomiting induced by carboplatin is much less severe than with cisplatin and rarely lasts beyond 24 hours. In a study of 943 ovarian cancer patients randomized to carboplatin, only 9% experienced greater than grade 2 nausea and/or vomiting (110). Emesis can usually be blocked entirely with aggressive therapy using antiemetic drug combinations (112). Diarrhea has been reported in only 6% of patients and constipation in 3% of carboplatin-treated patients (113).

Nephrotoxicity has been reported with carboplatin, but it is much less common and less severe than with cisplatin. In a large

review, transient elevations in serum creatinine and blood urea nitrogen were described in 7% and 16% of patients, respectively (113). Measured creatinine clearances dropped in 25% of patients, and a slight increase in uric acid was described in the same percentage of patients. However, there can be a significant loss of serum electrolytes, including potassium (16% of patients) and magnesium (37%). Serum calcium is only rarely decreased after carboplatin treatment (113).

A few cases of carboplatin-induced hematuria have been described. Hepatic enzyme elevations occasionally occur with carboplatin (113). Alkaline phosphatase was transiently increased in 36% of patients and serum glutamic oxaloacetic transaminase (SGOT) or serum glutamic pyruvic transaminase (SGPT) in about 15% of patients. Serum bilirubin levels are rarely elevated (4%) (113).

Neurotoxicity is uncommon after carboplatin and was described in only 25 of 428 (6%) patients treated on a variety of schedules for different tumor types (113). Mild paresthesias have been reported in a few patients receiving cumulative carboplatin doses of more than 1.6 g/m² (111). Unlike cisplatin, these peripheral nerve toxicities rarely produce any disabling symptoms. In most cases, no neurotoxicity was attributed to the drug.

Ototoxicity does not appear to be problematic with carboplatin, and only 8 of 710 (1.1%) patients have described clinical hearing deficits, mainly tinnitus (113). However, if pretreatment and serial audiometric tests are performed, as many as 15% of the patients may have some decrease in audio acuity. Fortunately, ototoxicity from carboplatin sometimes improves after therapy is halted. Like cisplatin, greater ototoxicity from carboplatin can be expected in patients with preexisting hearing loss or in those concurrently being given other ototoxic drugs, such as aminoglycosides.

Other rare carboplatin toxicities include alopecia (2% of patients), mucositis (2%), skin rash (1.7%), injection-site irritation without extravasation necrosis (0.4%), and a flu-like syndrome (1.3%) (113). The same study described alterations in taste sensation. Skin disorders from carboplatin treatment may appear as an erythematous rash in exposed areas and do not occur in all patients who had developed similar rashes on cisplatin (111).

Although carboplatin-associated hypersensitivity reactions rarely occur when the drug is administered as part of an initial chemotherapeutic regimen, subsequent administration of carboplatin in the setting of second-line or salvage therapy is associated with an increased risk of hypersensitivity. It has been estimated that greater than 25% of patients who receive more than 6 courses of platinum-based (i.e., cisplatin or carboplatin) chemotherapy develop sensitivity to carboplatin (114). The onset of symptoms may occur during the carboplatin infusion or up to 3 days after drug administration. Mild reactions consist of localized itching and erythema, primarily of the palms and soles, and/or facial flushing, whereas severe reactions can cause diffuse erythema, tachycardia, wheezing, facial edema, chills, rigors, throat and chest tightness, dyspnea, vomiting, alterations in blood pressure (both hypotension and hypertension), and in extreme cases, respiratory arrest. Mild cases may respond to IV diphenhydramine (50 mg) or oral diphenhydramine (25 to 50 mg every 4 to 6 hours), and additional courses of carboplatin can be administered. Severe hypersensitivity reactions typically necessitate the discontinuance of carboplatin; however, some patients are able to receive additional courses of carboplatin with administration of corticosteroids for several days prior to carboplatin administration. Hypersensitivity reactions may also occur when carboplatin is administered by the IP route (115).

Platinum-based chemotherapy (either cisplatin or carboplatin) has been shown to increase the risk of leukemia in ovarian cancer patients (116). Following carboplatin-based chemotherapy, the estimated relative risk of leukemia is 6.5 (95% confidence interval, 1.1 to 9.4). The relative risk increases as a function of

both cumulative dose and duration of treatment. Patients who receive 4,000 mg or more of carboplatin have a relative risk of 7.6 of developing leukemia, whereas patients who receive more than 12 months of carboplatin-based chemotherapy have a relative risk of 7.0. Although radiation therapy alone does not increase the risk of leukemia, radiation therapy administered in combination with platinum-based chemotherapy is associated with a significantly higher risk of leukemia than platinum-based chemotherapy without radiation ($p = 0.006$). The average time to onset of secondary leukemia is 4 years after the diagnosis of ovarian cancer. Although the potential benefits of platinum-based chemotherapy for ovarian cancer far outweigh the risk of secondary leukemia, the dose-dependent leukemogenic potential of platinum-based chemotherapy should be considered during its administration to patients with early-stage disease.

With the high doses of carboplatin used in autologous bone marrow transplantation programs, other severe toxicities may occur. These include hepatotoxicity (both hepatitis and cholestasis) and severe renal dysfunction (96,117). Nausea, vomiting, and electrolyte wasting are also more profound with high-dose carboplatin treatments. In addition, other unusual toxic effects may occur. These include hemorrhagic colitis, optic neuritis, and interstitial pneumonitis.

As noted below (see Drug Interactions), paclitaxel ameliorates carboplatin-induced thrombocytopenia.

Drug Interactions

Although the pharmacokinetics of carboplatin is not altered by coadministration of paclitaxel, patients who receive combination chemotherapy with carboplatin plus paclitaxel experience less thrombocytopenia than would be expected if carboplatin was administered as a single agent (103,118). The relationship between free platinum exposure and thrombocytopenia following carboplatin/paclitaxel chemotherapy can be described by a sigmoid maximum effect model (103). In that the degree of neutropenia appears to be unaffected by coadministration of paclitaxel and carboplatin, this pharmacodynamic interaction is believed to occur at the megakaryocyte level (118).

The cytoprotective agent amifostine reduces carboplatin-induced thrombocytopenia (119) but also extends the plasma half-life of carboplatin (120). In a randomized trial of carboplatin with or without amifostine, the median platelet nadir of patients treated with carboplatin 500 mg/m² was 88,000/ μ L, whereas the nadir in patients who received amifostine 910 mg/m² was 127,000/ μ L ($p = 0.023$) (119). Pharmacokinetic studies have shown that amifostine administered just before the carboplatin infusion and 2 to 4 hours thereafter is associated with a significant increase in the terminal half-life of the ultrafiltrable platinum species (e.g., in patients with a creatinine clearance less than 80 mL/min the platinum half-life increased from 4.2 to 5.6 hours with the addition of amifostine). In patients with good renal function, the impact of the increase in terminal half-life was associated with a minimal effect on the AUC. However, patients with impaired renal function experienced significant increases in the AUC of the ultrafiltrable platinum species (120).

Special Applications

Patients with advanced ovarian cancer have been treated with IP carboplatin in doses ranging from 200 to 650 mg/m² (121). Pharmacologic studies have demonstrated that serum concentrations are equivalent between IV and IP carboplatin regimens, but IP administration results in more than 10 times the concentration in the peritoneal cavity compared to IV administration (122). However, cisplatin may be a better choice for IP delivery in that it appears to have significantly better penetration into tumor masses than carboplatin (123). Several early-phase trials have shown potentially promising results (17,124); however, there is a need for phase III research to determine the

possible efficacy of IP carboplatin and trials to determine the optimal dosing schedule.

Because of its relative lack of nonhematologic side effects, carboplatin has become the platinum analog of choice for bone marrow transplantation regimens. A regimen developed at Loyola University that consists of high-dose carboplatin combined with cyclophosphamide, mitoxantrone, and autologous bone marrow support was selected for an intergroup phase III study of high-dose versus standard-dose chemotherapy for ovarian cancer patients with low-volume, persistent disease following primary chemotherapy (GOG-164). Although this study was closed in May 1999 because of inadequate patient accrual, the high-dose regimen was well tolerated among the 24 patients on the trial. With adequate hydration and mannitol diuresis to prevent nephrotoxicity, nonhematologic side effects were predominantly mucositis, ototoxicity, and diarrhea (117).

Cisplatin

Chemistry

Cisplatin (Platinol, *cis*-diamminedichloroplatinum II) is a primary drug in the treatment of advanced cancer of the ovary, cervix, and endometrium. It has the molecular formula PtCl₂H₆N₂ (molecular weight = 300.1). It is a planar inorganic heavy metal complex containing a central atom of platinum surrounded by 2 chloride atoms and 2 ammonia molecules in the *cis* position. It is soluble in water at a concentration of 1 mg/mL. Only the *cis*-isomer is therapeutically active.

Mechanism of Action

Cisplatin's interaction with DNA is probably its primary mode of action. The antitumor effect of cisplatin has been correlated with binding to DNA and the production of intrastrand cross-links and formation of DNA adducts, similar to carboplatin (94,125). Intrastrand cisplatin adducts can cause changes in DNA conformation that may affect DNA replication (126). Platinum DNA adduct levels have been measured in patients' leukocytes and correlated with clinical response (125).

Mechanisms of cisplatin drug resistance are an area of concentrated research. Methods by which tumor cells may develop resistance to platinum agents include decreased drug accumulation, increased glutathione levels, enhanced DNA repair, and increased capacity to tolerate DNA damage (127,128).

The ERCC1 repair protein is part of the nucleotide excision repair system, which takes part in single-strand break repair. It is thought that this system may be responsible for the removal of intrastrand DNA platinum adducts from DNA. High expression of ERCC1 has been associated with platinum resistance and poorer survival in ovarian cancer patients treated with platinum-based regimens (129) [H10]. ERCC1 has also been identified as playing a critical role in the synergy of gemcitabine and cisplatin. Phase II data suggest that gemcitabine may reverse cisplatin resistance, as gemcitabine-cisplatin combination therapy was active in platinum-resistant ovarian cancer patients (130).

Resistance to platinum drugs has also been associated with the activity of the double-strand break repair system, homologous recombination repair (HR). Tumors arising in patients with germline BRCA1 and BRCA2 mutations respond better to platinum-based therapy and survive longer on treatment than their BRCA wild-type counterparts (131–133). Both BRCA1 and BRCA2 are involved in HR, and patients whose tumors contain somatic BRCA1/2 mutations or who show impaired HR ("BRCAness") also respond better and survive longer on platinum-based therapy than case controls (134,135). The idea that platinum resistance may be mediated by HR is supported by the observation of secondary mutations that re-activate either the BRCA1 (136) or the BRCA2 (137,138) proteins when these patients eventually become resistant to platinum drugs.

In vitro studies have shown that the copper transporter, CTR1, plays a regulatory role with respect to the uptake of platinum drugs (139). In a study of 40 patients with ovarian carcinoma, Yoo-Young Lee et al. showed that high CTR1 expression was specifically associated with sensitivity to platinum-based therapy and prolonged progression-free survival while low CTR1 expression and high STR2 expression were associated with resistance to platinum-based therapy and shorter survival (140).

Mechanisms of resistance also include the increased inactivation of thiol-containing proteins such as glutathione and glutathione-related enzymes, a deficiency in mismatch repair enzymes (e.g., hMLH1, hMSH2), and decreased drug accumulation due to alterations in cellular transport (79).

A study of hMLH1 methylation in the plasma DNA of ovarian cancer patients at presentation and relapse showed no correlation with outcome at presentation, but high methylation was associated with poorer outcome following relapse (141). Whether this was due to resistance to platinum drugs is not clear because the report does not document the treatments given following relapse. Further, a follow-on randomized phase II study using decitabine to induce demethylation of the HMLH1 promoter showed an inferior outcome in the decitabine arm (142). The clinical relevance of mismatch repair defects in the response to platinum agents remains uncertain.

Recent evidence also suggests that resistance to platinum and other agents may be mediated by factors in the tumor environment rather than in the tumor cell itself. Roodhart et al. have identified 2 distinct platinum-induced polyunsaturated fatty acids (PIFAs), 12-oxo-5,8,10-heptadecatrienoic acid (KHT) and hexadeca-4,7,10,13-tetraenoic acid (16:4[n-3]), that in minute quantities induce resistance to a broad spectrum of chemotherapeutic agents, including platinum agents (143).

Drug Disposition

Cisplatin demonstrates a triphasic disappearance curve with a $t_{1/2\alpha}$ of 20 minutes, a $t_{1/2\beta}$ of 48 to 70 minutes, and a terminal-phase half-life of 24 hours (144). The first 2 phases of disappearance represent clearance of free drug from the plasma, and the third phase is probably removal of drug from the plasma proteins. The ratio of cisplatin to total free platinum in plasma has a great deal of interpatient variability: from 0.5 to 1.1 after a dose of 100 mg/m². Three hours after a bolus injection and 2 hours after a 3-hour infusion, 90% of the plasma protein is bound to the platinum in cisplatin, not the cisplatin itself. The complexes between albumin and platinum are slowly eliminated with a minimum half-life of 5 days or more (145). Ninety percent of the drug that is excreted is removed by renal mechanisms (i.e., glomerular filtration and tubular secretion), and less than 10% is removed by biliary excretion. Fecal excretion appears to be insignificant. The total proportion of a given dose that is excreted is variable and has been reported to be between 31% and 85% after 51 days (146). The remainder stays bound to tissues for very long periods. Schierl et al. reported 2 long-term biological half-lives of platinum of 16 and 720 days and showed that, of an administered dose of 800 mg cisplatin, 1 mg remained in a long-term pool after 3,000 days (147). There is a potential for accumulation of ultrafilterable platinum plasma concentrations whenever cisplatin is administered on a daily basis but not when dosed on an intermittent schedule.

Administration and Dosage

Cisplatin may be administered IV or IP. Cisplatin should be mixed only in solutions containing 0.9% or more sodium chloride, because drug stability is directly related to the concentration of the salt. When admixed with dextrose-containing solutions, by chromatographic analysis, the drug appears to be relatively unstable, with decomposition evident by 2 hours (148). Platinum also can form significant, colored

complexes if directly admixed with mannitol and stored for 2 to 3 days (149). Short-term (<24 hours) admixtures, however, have been successfully used. Needles or IV sets containing aluminum should not be used in the preparation or administration of cisplatin, because this drug rapidly reacts with aluminum, resulting in a loss of drug potency and the formation of a black precipitate (150).

To protect against nephrotoxicity, it is critical that a high urinary output be maintained during cisplatin therapy. Several methods of accomplishing this have been recommended; however, the most widely practiced method involves prehydration and mannitol diuresis (151). If cisplatin is administered in a hospital setting, patients should receive hydration with 1 to 2 L of fluid prior to cisplatin. Mannitol diuresis is accomplished by diluting the cisplatin in 2 L of normal saline containing 37.5 g of mannitol. The solution is then infused over 6 to 8 hours. Adequate hydration and urinary output should be maintained during the next 24 hours. A safe outpatient procedure using concurrent mannitol that appears to prevent serious nephrotoxicity has also been reported (152). The desired dose of cisplatin plus 50 g mannitol is diluted to 1 L with 5% dextrose plus 0.45% sodium chloride, USP. This solution may then be infused at a rate of no more than 1 mg/min. For patients with known cardiac disease, the dose may be placed in 200 mL of a 10% mannitol solution and infused at a rate of no more than 1 mg/min. This is followed by 200 mL of additional 10% mannitol. An alternative is to add the drug to 400 mL of 10% mannitol that is then brought up to a 1-L volume with normal saline containing 3 g of magnesium sulfate and administered IV over 1 hour (153).

Intraperitoneal cisplatin administration and nursing guidelines are described in detail elsewhere (154,155), using the GOG-172 regimen adapted to a 3-hour paclitaxel infusion (IV paclitaxel 135 mg/m² over 3 hours day 1 + IP cisplatin 100 mg/m² day 2 + IV paclitaxel 60 mg/m² day 8). A totally implantable device (IV port, such as single-lumen venous-access catheter: 9.6F, Port-A-Cath or Bardport) is surgically placed in the IP space at least 2 days before cisplatin administration. Placement can be done at the time of surgery or postoperatively (e.g., laparoscopically). It is important to note that peritoneal or fenestrated catheters can lead to fibrous sheath formation, small bowel obstruction and perforation, and should be avoided (156). Day 2 IP administration requires that cisplatin be mixed in 1 L of normal saline and then warmed to body temperature. The 1-L cisplatin solution is instilled as rapidly as possible into the IP space via the catheter and should be followed by up to one additional liter of saline to the point of mild abdominal discomfort. The cisplatin solution is allowed to remain in the IP cavity (i.e., the fluid is not drained). Concurrently, at least 1 L normal saline must be administered IV along with 40 gm mannitol to assure a brisk diuresis to eliminate the cisplatin. Since cisplatin has the potential to be highly emetogenic, it is important to consider an aggressive antiemetic regimen (154,157).

A retrospective analysis by Levin and Hryniuk (158) strongly suggests that cisplatin efficacy against ovarian cancer is directly correlated with cisplatin dose intensity (i.e., mg/m²/wk). Typical high-dose regimens include 20 mg/m² daily for 5 days repeated every 3 weeks, 100 to 120 mg/m² IV every 3 to 4 weeks, or 100 mg/m² on day 1 and day 8 repeated every 20 days (159,160). Holleran and DeGregorio (161) prepared an excellent review of high-dose (200 mg/m²/course) cisplatin. Dose-limiting toxicities with the higher dose regimens include severe, relatively irreversible neurotoxicity and myelosuppression. Responses have been seen in conventional-dose cisplatin-refractory patients, but they generally are of relatively short duration.

Side Effects and Toxicities

Dose-related nephrotoxicity is the major dose-limiting toxicity of cisplatin. It is manifested by renal tubular damage resulting in

an elevation of BUN (blood urea nitrogen) or serum creatinine. The peak detrimental effect on renal function usually occurs between the tenth and twentieth day after treatment. The renal damage is usually reversible. Patients concomitantly receiving gentamicin and cephalothin have been shown to be at greater risk of developing acute renal failure (162).

Madias and Harrington (163) have characterized the renal damage of cisplatin as being similar to mercury nephrotoxicity. Pathologically, renal tubular necrosis, degeneration, and interstitial edema without glomerular changes are observed. Although clinically overt renal toxicity may be common, it is usually reversible. However, some degree of long-term damage is likely. The renal-protective effect of hydration and mannitol is well established in animals and humans, and renal impairment can be prevented (152).

Ototoxicity, manifested by high-frequency hearing loss (above the frequency of normal speech), may be seen in as many as 30% of patients treated with cisplatin (164). Hearing impairment may be dose related and can be unilateral or bilateral. Occasional tinnitus (but not vestibular dysfunction) has been reported. The ototoxicity may be partially reduced by adequate hydration and the use of mannitol diuresis. Patients with lower than average threshold before chemotherapy with cisplatin are more likely to experience greater threshold shifts (164).

Neurotoxicity can be a dose-limiting side effect of cisplatin, particularly with high-dose regimens (165). The range of cisplatin-induced neurologic deficits include peripheral sensory neuropathy, ototoxicity, autonomic neuropathy manifested by orthostatic hypotension and gastric paresis, Lhermitte's syndrome, and rarely focal encephalopathy, often accompanied by cortical blindness. Peripheral neuropathy is by far the most common cisplatin-induced neurotoxicity. Neurotoxicity is dose dependent, with symptoms typically developing after cumulative doses of 300 mg/m² or more. A review of published literature (166) found that neurotoxicity occurred in 85% of patients at cumulative doses of 300 mg/m² or more but occurred in only 15% of patients who had received a cumulative dose below this level. Initial symptoms are usually numbness and tingling in the distal fingers and toes. If cisplatin is continued, proximal extension of the peripheral neuropathy occurs, and the sense of joint position becomes impaired, resulting in more severe neurologic symptoms, including ataxia, gait disturbances, loss of manual dexterity, and wheelchair dependency. Symptoms may begin and progress up to 4 or more months after discontinuation of cisplatin. In 30% to 50% of patients, cisplatin neuropathy is irreversible.

Early clinical data suggest that a number of investigational agents may ameliorate cisplatin-induced neurotoxicity (165). Agents that have been associated with positive preclinical results include ORG2766 (167), an ACTH analog, and the sulfhydryl-based compounds amifostine and glutathione. Only amifostine has been associated with a significant reduction of grades 2 and 3 neurotoxicity in the setting of an adequately designed phase III trial (168). Further development of a neuroprotective agent, such as amifostine, could significantly enhance the clinical effectiveness of cisplatin, enabling dose-intensive therapy and greater cumulative doses to be delivered to more patients with sensitive tumors. In 2003, the GOG initiated a phase III trial of low-dose, IV bolus amifostine 3 times weekly to reverse grade 2 or greater peripheral neuropathy (GOG-192).

Symptomatic hypomagnesemia frequently occurs with cisplatin. In a study to determine the effects of magnesium supplementation on cisplatin-induced hypomagnesemia, the administration of magnesium (oral and IV) with cisplatin to one group of patients produced less renal tubular damage and no compromise in efficacy than that seen in a group not supplemented with magnesium (169).

Without adequate antiemetic therapy, most patients who receive cisplatin experience nausea and vomiting. This reaction may be severe and usually starts within the first hour after

treatment and may persist for 24 to 48 hours. Delayed nausea and vomiting, lasting from 3 to 5 days, also may occur. The combination of a 5-HT₃ inhibitor (e.g., ondansetron or granisetron) with dexamethasone (10 to 40 mg IV) has reduced the incidence of severe nausea and vomiting by as much as 75% (170). Delayed nausea and vomiting can be eradicated by continuation of oral low-dose dexamethasone (with or without a 5-HT₃ inhibitor) for the first 5 days after platinum treatment (171). Other less effective antiemetic regimens to prevent cisplatin-induced nausea and vomiting include prochlorperazine, dexamethasone, and lorazepam; metoclopramide and dexamethasone; metoclopramide and methylprednisolone; or metoclopramide and lorazepam (112,172).

Anaphylactic hypersensitivity reactions consisting of tachycardia, wheezing, hypotension, and facial edema, occurring within a few minutes of IV administration, have occurred occasionally after a dose of cisplatin given to previously treated patients (173,174). These hypersensitivity reactions have been controlled with corticosteroids, epinephrine, or antihistamines. Wiesenfeld and colleagues (175) reported successful retreatment with cisplatin after apparent allergic reactions in 2 patients. *In vivo* and *in vitro* tests in one patient could not demonstrate an immunologic basis for the initial reaction. Both patients were successfully rechallenged with cisplatin after only diphenhydramine pretreatment. This suggests a nonallergic cause of the acute hypersensitivity reactions occasionally seen with platinum.

Myelosuppression occurs in 25% to 30% of patients receiving the recommended dose, and is more pronounced at higher doses. Coombs-positive hemolytic anemia also occurs as a result of cisplatin treatment. Cisplatin-induced anemia has been shown to respond to recombinant erythropoietin (176).

Drug Interactions

When cisplatin is given in combination with other agents, the order of drug sequence can affect the severity of drug-induced myelosuppression. Rowinsky and Donehower (177) conducted a phase I study of sequential escalating doses of paclitaxel and cisplatin therapy and determined that myelosuppression was more severe when cisplatin administration preceded paclitaxel than when given after paclitaxel. Another phase I study was conducted to evaluate the effects of drug sequence of treatment with cisplatin in combination with topotecan (178). This study also found a significantly higher incidence of myelosuppression when cisplatin was administered first.

Cisplatin-induced nephrotoxicity should be considered whenever this agent is given prior to or in combination with other cytotoxic drugs that are cleared by renal elimination (e.g., bleomycin, ifosfamide, etoposide, methotrexate). Cisplatin reduces the renal clearance of these agents, resulting in an increased accumulation of these drugs. Yee and coworkers (75) observed markedly reduced bleomycin clearance in children who had received 6 courses of a regimen including cisplatin (cumulative dose 300 mg/m²). In another case report, fatal bleomycin pulmonary toxicity occurred in a patient with cisplatin-induced acute renal failure (76).

Cisplatin is directly inactivated by mesna and amifostine (79). The FDA has approved amifostine to reduce the cumulative renal toxicity associated with repeated administration of cisplatin in patients with advanced ovarian cancer. In a phase III randomized study of ovarian cancer patients, amifostine treatment prior to IV cisplatin plus cyclophosphamide did not appear to reduce cisplatin's anticancer activity (179). However, there are only limited data in other chemotherapeutic settings, and the FDA recommends that amifostine should not be administered to patients in settings where chemotherapy could produce a significant survival advantage or cure, except in a clinical trial (180).

Special Applications

The efficacy of cisplatin can be increased significantly in patients with stage III, optimal disease (i.e., <1 cm² residual

tumor) epithelial ovarian cancer when it is administered by the IP route as part of a primary, combination chemotherapy regimen. A pivotal phase III trial, GOG-172, determined that the IP administration of cisplatin 100 mg/m² (on day 2, preceded by IV paclitaxel 135 mg/m² over 24 hours on day 1 and followed by IP paclitaxel 60 mg/m² on day 8, every 3 weeks for 6 cycles) was associated with a highly significant 16-month increase in overall survival compared with the standard treatment arm (IV cisplatin 75 mg/m² plus IV paclitaxel 135 mg/m² over 24 hours every 3 weeks for 6 cycles) in patients with advanced, optimal ovarian cancer (4). Despite the higher incidence of toxicity in the IP arm, these effects appear to be of short duration, as patients treated IP and IV reported equivalent quality of life 1 year post treatment (8). As a result, the National Cancer Institute issued a Clinical Announcement on January 5, 2006 recommending IP therapy as the preferred treatment for optimal, advanced ovarian cancer (181).

Intraperitoneal therapy is not recommended for patients who have suboptimal cytoreductive surgery (i.e., >1 cm in largest diameter of a tumor nodule), because IP cisplatin (as well as other cytotoxic agents) only penetrates a few millimeters into tumor plaques (16). Additional considerations regarding the appropriate patient selection for consideration of IP therapy are discussed in detail elsewhere (154,155,182).

Multiple phase III studies have shown that cisplatin-based chemotherapy as an adjunct to radiation therapy improves survival in cervical cancer patients (47,183–185).

Cyclophosphamide

Chemistry

Cyclophosphamide (Cytosan, Neosar, CTX, CPM, and Endoxan) is an alkylating agent that before the advent of paclitaxel was used in the primary chemotherapy of advanced, epithelial-type ovarian and endometrial cancer. It is no longer often used in the treatment of gynecologic cancers because of the more effective agents currently available (e.g., paclitaxel). It is occasionally used in the third-line treatment of ovarian cancer and as a second-line agent in the treatment of choriocarcinoma. It is a cyclic phosphamide ester of nitrogen mustard and is referred to chemically as 2-[bis-(2-chloroethyl)amino]tetrahydro-2H-1,3,2-oxazaphosphorine 2-oxide monohydrate. Its molecular weight is 279.1. The monohydrate is unionized and lipid soluble; in normal saline or water, it is soluble to a maximum of 4% at room temperature.

Mechanism of Action

Cyclophosphamide, a bifunctional substituted nitrogen mustard, was synthesized in 1958 in an attempt to achieve greater selective toxicity for tumor tissue. The N-methyl moiety of nitrogen mustard is replaced with a cyclic phosphamide group, resulting in a stable, inactive compound. The bis-(2-chloroethyl) group cannot ionize until the cyclic phosphamide is opened at the phosphorus-nitrogen linkage.

Activation of cyclophosphamide is a multistep process. The liver microsomal P450 mixed-function oxidase system converts the parent drug to 4-hydroxycyclophosphamide. This metabolite exists in equilibrium with the acyclic tautomer, aldophosphamide. These compounds may be further oxidized by hepatic aldehyde oxidase to the inactive metabolites of carboxyphosphamide and 4-ketocyclophosphamide. Nonenzymatic conversion to the cytotoxic compounds of phosphoramidate mustard and acrolein occurs in susceptible peripheral tissues.

Most of the alkylating agents, like cyclophosphamide, are bifunctional, which facilitates their reaction with 2 cellular molecules. Accordingly, they can cross-link the 2 opposite strands of DNA to give an interstrand cross-link, react with 2 sites on the same strand (intrastrand cross-link), or cross-link DNA to

protein. The latter type of lesion is generally considered to be innocuous, but the relative significance of the other cross-links is still in contention. DNA intrastrand cross-links are more frequent than interstrand cross-links and are more often considered to be the critical lesions.

These 2 classes can be differentiated by the structure of the cross-links in DNA. Generally, the entire mustard is involved in the cross-link, with the 2 mustard “arms” linked usually to the N7 position of guanine. Since these guanines can be separated by several bases in DNA, the linkages represent particularly bulky lesions.

Drug Disposition

After IV administration, approximately 15% of the drug is excreted unchanged in the urine and the remainder as metabolites. The plasma half-life of the parent compound after doses of 6 to 80 mg/kg appears to range from 4.0 to 6.5 hours (186,187). Approximately 50% of the alkylating metabolites (but not parent drug) is bound to plasma proteins.

Although cyclophosphamide is exclusively excreted by the kidney, because of the unionized nature of the intact drug molecule, tubular reabsorption is avid. Hepatic inactivation appears to be the major mechanism of active drug elimination. The mean renal clearance of intact drug is approximately 11 mL/min, or 15% of creatinine clearance, but renal elimination remains the major route of disposition of the more polar, less lipid-soluble metabolites (188). There can be significantly prolonged retention of active (alkylating) metabolites in patients with severe renal failure, and doses should be adjusted accordingly.

Dosage

Cyclophosphamide is active in many different types of malignancies. The dosing schemes are numerous and depend on the particular disease. There are two general categories of treatment schedules exist. In the method generally used to treat ovarian and endometrial cancers, an intermediate dose (600 to 1,000 mg/m²) is given all at once over a short period. This treatment approach usually involves other drugs, such as cisplatin, carboplatin, or doxorubicin, whose additive toxic effects must be considered in selecting the dose and frequency of cyclophosphamide administration. Adequate hydration for 72 hours before and following high-dose treatment with cyclophosphamide is recommended to reduce cyclophosphamide-induced hemorrhagic cystitis (189).

An alternative continuous low-dose regimen for cyclophosphamide has been developed. Doses of 25 to 50 mg/day are given on a continuous basis. Used in this way, it was originally thought that cyclophosphamide acted as an “accidental” antiangiogenic agent (190). It is usually well tolerated with few side effects. Colleoni and colleagues published the results of a trial of continuous low-dose cyclophosphamide with methotrexate in breast cancer and showed antitumor activity that correlated with vascular endothelial growth factor levels (191). Further, Miscoria and colleagues found an association between progression-free survival and thymidine phosphorylase levels (192). A suggestion has been made that the acrolein metabolite of cyclophosphamide acts as an antiangiogenic agent (193). The use of cyclophosphamide in this way has come to be known as “metronomic” dosing. In addition to the antiangiogenic effect, metronomic cyclophosphamide may also have an immune regulatory function (194). Ge et al. (195) showed that metronomic cyclophosphamide induced an increase in the number of breast cancer reactive t-cells and that this correlated with disease stabilization in breast cancer.

There have been a large number of trials of the metronomic approach in a range of tumor types, including ovarian cancer. These have been reviewed (196). Activity is frequently reported, but the heterogeneous nature of the trials, the frequent combination with established antiangiogenic agents,

and the lack of randomized trials makes the overall role of this approach undefined.

Side Effects and Toxicities

Myelosuppression consisting primarily of leukopenia is the usual dose-limiting toxic effect of cyclophosphamide. Both the nadir and time of bone marrow recovery are rapid at 8 to 14 and 18 to 21 days, respectively. Although this drug has long been considered to be “platelet sparing,” significant thrombocytopenia can also occur at very high doses ($>1.5 \text{ g/m}^2$).

Acute, sterile hemorrhagic cystitis, believed to be due to the acrolein metabolite, is an infrequent toxic manifestation, but is occasionally dose limiting. It is understandably more common in poorly hydrated or renally compromised patients. The onset of this complication may be delayed from 24 hours to several weeks. It is detected by gross hematuria or a microscopic hematuria of greater than 20 erythrocytes per high-power field. The bleeding may persist but is usually transient. Prophylactic hydration with intake of at least 3 L/day appears to offer the best protection. With continued therapy, patients characteristically develop a fibrotic “small bladder,” and urinary frequency may become a permanent problem. There is a definite increase in the risk of bladder cancer in these patients. The availability of the sulfhydryl mesna as a prophylactic treatment of patients at high risk for developing cyclophosphamide-induced cystitis has almost completely eliminated this side effect.

A syndrome of inappropriate antidiuretic hormone (SIADH), or “water intoxication,” has been reported after cyclophosphamide treatment. This is more common with IV doses greater than 50 mg/kg and is both a limitation to and consequence of fluid loading (197). Alopecia occurs to some degree in all patients receiving cyclophosphamide and is significant in at least half of all patients treated. Regrowth of hair may occur even with continuing treatment. Gastrointestinal problems are more common with high doses given orally. Anorexia, nausea, and vomiting are all common reactions, but they are usually controlled with IV antiemetic regimens. A rare pulmonary toxic effect has been reported with a pneumonitis picture similar to “busulfan lung.” The typical clinical presentation is that of an interstitial pneumonitis, usually occurring after long-term and continuous low-dose therapy (198). The onset of symptoms is insidious. Pathologically, there can be alveolitis with eventual fibrosis and atypical type II pneumocytes. Steroids may be beneficial. Other toxic effects include testicular atrophy, sometimes with reversible oligospermia and azospermia. Amenorrhea also has been reported. As with all alkylating agents, drug-induced congenital abnormalities are possible. With high-dose therapy used for bone marrow transplant (120 to 180 mg/kg), cyclophosphamide-associated cardiac toxicity has been reported (199).

Special Precautions

It is important to keep the patient well hydrated during cyclophosphamide therapy to reduce the potential for hemorrhagic cystitis. It is advisable to administer at least 1 L of additional IV fluids (usually normal saline) to assure an adequate urine volume to excrete the cyclophosphamide metabolite acrolein, which can otherwise alkylate bladder mucosa and cause hemorrhagic cystitis. The patient should be instructed to drink at least 8 glasses of fluid daily during the 2 days after cyclophosphamide administration. In patients prone to developing cystitis, consider administering prophylactic IV mesna, a sulfhydryl-containing compound that can neutralize acrolein.

Drug Interactions

Cyclophosphamide must be metabolized to be active. Although some cyclophosphamide may be activated by phosphatases and phosphamidases peripherally, most of the drug is metabolized

by microsomal enzymes in the liver (200,201). These enzymes may be activated by drugs like phenobarbital or inhibited by drugs like proadifen (SKF 525A). Because active and toxic metabolites are generated by the reactions of these enzymes and cyclophosphamide, many potential drug interactions may exist.

Barbiturates and other inducers of hepatic microsomal enzymes, such as phenytoin and chloral hydrate, may increase the rate of hepatic conversion of cyclophosphamide to its toxic metabolites. Similarly, cyclophosphamide may block the metabolism of barbiturates, increasing sedative effects. Although the clinical significance of these reactions is not clear, cyclophosphamide toxicity may be increased by the H_2 -histamine blocker cimetidine (202). Cimetidine, but not ranitidine, may increase cyclophosphamide’s myelotoxicity through an increase in the concentration time product of its active metabolites (e.g., 4-hydroxycyclophosphamide and phosphoramidate mustard) (203). Thus, H_2 -blockers such as ranitidine may be safer to use than cimetidine when high doses of cyclophosphamide are administered.

Dactinomycin

Chemistry

Dactinomycin (actinomycin D, ACT-D, Cosmegen) has been shown to be active in the treatment of patients with germ-cell tumors of the ovary and endometrium and those with gestational trophoblastic disease (204–206). It has a molecular weight of 1,255 and an empiric formula of $\text{C}_{62}\text{H}_{86}\text{N}_{12}\text{O}_{16}$. The drug is an antitumor antibiotic isolated from *Streptomyces parvulus*. The molecular structure includes 2 peptide loops linked to a 3-ring chromophoric phenoxazone ring system (actinocin). The drug is highly soluble in water, forming an amber- to gold-colored solution.

Mechanism of Action

Dactinomycin becomes anchored into or around a purine-pyrimidine base pair in DNA by intercalation. DNA-dependent ribosomal RNA synthesis and new messenger RNA synthesis is inhibited. The peptide loops appear to allow tight drug binding to DNA because the actinocin (phenoxazone) moiety alone is inactive. This can occur adjacent to any G–C pair in DNA.

Bound dactinomycin molecules dissociate very slowly from DNA owing to electrostatic interactions of the cyclic peptide rings with each strand of the DNA double helix. This process, which stabilizes the intercalative interaction, appears to be crucial for cytotoxicity.

Dactinomycin on a molar basis is one of the most potent antineoplastic agents available. The drug possesses some hypocalcemic activity, similar to mithramycin. Although maximal cell killing is observed in the G_1 phase, the cytotoxic action is thought to be primarily cell cycle nonspecific. Actively proliferating cells are more sensitive than quiescent cells to the lethal effects of the drug (207).

In that dactinomycin is a natural product, it is not surprising that the primary mode of tumor cell resistance to dactinomycin is mediated through overexpression of P-glycoprotein (208).

Drug Disposition

Tattersall and colleagues (209) studied the pharmacokinetics of radiolabeled [^3H] dactinomycin in patients, and the drug appeared to be only minimally metabolized and was concentrated in nucleated cells. There was a greater drug uptake into bone marrow than in plasma. Drug penetration into the central nervous system was not observed. Urinary and fecal recovery totaled only 30% each after 9 days, and there was significant drug retention in lymphocytes and granulocytes. This may explain the prolonged terminal plasma half-life of 36 hours observed after single dactinomycin doses. There appears to be little metabolism, because approximately 90% of excreted drug

is collected as the intact molecule. Some monolactone forms of dactinomycin are recovered in the urine.

Using a more specific radioimmunoassay, a much shorter dactinomycin half-life is described ($t_{1/2\alpha} = 0.78$ minutes, $t_{1/2\beta} = 3.5$ hours) (210). The discrepancies between these and Tattersall's findings reflect the differences in the assays used.

Administration and Dosage

Dactinomycin is administered by slow IV push or, preferably, into the tubing of a freely running IV solution. A 5- to 10-mL flush of 5% dextrose in water (D₅W) or normal saline is recommended before and after IV push administration to assure vein patency and to flush any remaining drug from the tubing.

Dactinomycin is commonly given IV in short "pulse" doses of 500 $\mu\text{g}/\text{m}^2$ daily for as long as 5 days in adults. The dose for each 2-week cycle should not exceed 15 $\mu\text{g}/\text{kg}/\text{day}$ or 400 to 600 $\mu\text{g}/\text{m}^2/\text{day}$ for 5 days.

A wide variety of dosing regimens have been employed. Several clinical studies have documented equal efficacy and toxicity for single-dose dactinomycin regimens (211,212). In non-metastatic gestational trophoblastic cancer, a single IV dose of 1.25 mg/m^2 every 14 days produced a 99% remission rate after 4 courses of therapy (212). Compared with 5 divided doses of 500 $\mu\text{g}/\text{m}^2/\text{day}$, the single-dose method produced slightly greater mild-to-moderate toxic effects.

Side Effects and Toxicities

Bone marrow depression is the usual dose-limiting toxic effect of dactinomycin. It is usually manifested 7 to 10 days after dosing. All blood elements are affected, but primarily, the platelets and leukocytes are depressed. Combined with gastrointestinal reactions, myelosuppression appears to be dose limiting as well as dose dependent (213). Immunosuppression is another well-known effect of dactinomycin. Patients should not receive this drug during viral infection because of the risk of developing disseminated disease.

Severe gastrointestinal consequences, such as vomiting, can occasionally represent the acute dose-limiting toxic effects of dactinomycin. Vomiting can persist for 4 to 20 hours, but it can be controlled by combination antiemetic regimens (214). Mucositis can also be severe. It is characterized by severe oral ulcerations and diarrhea in 30% of patients. Reversible alopecia may occur with dactinomycin. A variety of other skin manifestations have been reported, including acneiform changes, erythema, and hyperpigmentation.

Dactinomycin is toxicologically similar to the anthracyclines and characteristically interacts with radiation therapy, producing delayed "radiation recall" skin damage. Previously irradiated or even irritated skin may become reddened and inflamed after drug administration. Frank necrosis is sometimes reported. Oral ulcers may also develop after radiation therapy. These reactions may occur months after radiation therapy. Experimentally, radiation therapy given after dactinomycin does not produce this effect.

Dactinomycin potentiates pulmonary radiation and decreases radiation tolerance by at least 20%. Reintroduction of dactinomycin following pulmonary radiation has resulted in fatal pulmonary fibrosis (215). As noted in the "Special Precautions" section below, dactinomycin is highly ulcerogenic if extravasated.

Special Precautions

Dactinomycin is extremely damaging to soft tissue, and every effort should be made to assure vein patency during administration. Extravasations characteristically result in immediate pain and swelling followed by indolent, poorly healing necrotic ulcers (214).

Dactinomycin is highly potent and is typically dosed in micrograms per kilogram. Doses must be calculated and prepared carefully to prevent inadvertent overdosage. No specific antidote to overdosage is known, although granulocyte colony-stimulating factors may be useful.

Dactinomycin is a potent immunosuppressant and can inhibit the effectiveness of vaccinations given after drug administration. The drug also produces radiation recall skin and soft-tissue damage if given after ionizing radiation.

Docetaxel

Chemistry

Docetaxel (Taxotere) is a semisynthetic analog of paclitaxel and has a FDA-approved indication for locally advanced or metastatic breast cancer after failure of prior chemotherapy. It is also FDA approved for locally advanced or metastatic non-small cell lung cancer after failure of prior platinum-based chemotherapy. It also has shown marked antitumor activity against a variety of solid tumors, including both platinum-sensitive and platinum-refractory epithelial ovarian cancer (216,217). The natural component of docetaxel is 10-deacetyl baccatin III, which is extracted from the needles of the European yew tree (*Taxus baccata* L.) (217). Docetaxel has a molecular weight of 861.9 and the empirical formula $\text{C}_{43}\text{H}_{53}\text{NO}_{14} \cdot 3\text{H}_2\text{O}$. Unlike paclitaxel, which uses a polyoxyl compound (Cremophor) as a diluent, docetaxel is formulated in Tween 80 and alcohol.

Mechanism of Action

In a manner similar to paclitaxel, docetaxel promotes microtubule assembly and inhibits the depolymerization of tubulin. However, compared with paclitaxel, the microtubules formed by docetaxel are more slowly reversible, and there are differential effects on tau binding sites and on microtubule-associated proteins. Docetaxel-induced stabilization of microtubules halts cellular division in M phase, thereby preventing cell replication.

Drug Disposition

The pharmacokinetics of docetaxel when administered as an IV infusion lasting from 1 to 24 hours has been investigated in a number of studies (218). When administered as a typical 1-hour infusion at doses of 70 to 100 mg/m^2 , pharmacokinetics reveals triphasic elimination with plasma AUC of 3.13 to 4.83 $\text{mg}/\text{mL}/\text{hour}$, a peak plasma concentration of 2.57 to 3.67 $\mu\text{g}/\text{mL}$, and a terminal-phase plasma half-life of 13.6 hours. There is very limited renal excretion of docetaxel; the 24-hour urinary excretion was 1.4% of the dose administered. Plasma drug clearance was determined to be 21.3 $\text{L}/\text{hour}/\text{m}^2$ (219).

Administration and Dosage

All patients receiving docetaxel should be premedicated with oral corticosteroids such as dexamethasone 16 mg/day (e.g., 8 mg BID) for 3 days beginning 1 day prior to docetaxel administration in order to reduce fluid retention and the risk of hypersensitivity reactions.

Docetaxel is commercially available in single-dose 20- and 80-mg vials with accompanying diluent vials. Both the docetaxel vials and the diluent vials should stand at room temperature for approximately 5 minutes prior to mixing. The entire contents of the diluent vial should be aseptically transferred to the docetaxel vial, and the resulting contents should be gently rotated for 15 seconds to promote complete mixture. The resulting concentration of docetaxel is 10 mg/mL . Foam may be present owing to the Tween 80; however, it should largely dissipate within a few minutes. The infusion solution is prepared by aseptically withdrawing the proper amount of docetaxel with a calibrated syringe and adding it to a 250-mL infusion bag or

bottle containing either 0.9% sodium chloride or 5% dextrose solution to produce a final concentration of 0.3 to 0.9 mg/mL. The infusion solution should be mixed by manual rotation and inspected for particulate formation and/or discoloration. Solutions that are cloudy or that contain particulate matter should be discarded.

The recommended dose of docetaxel for salvage chemotherapy of breast cancer is 60 to 100 mg/m² IV as a continuous 1-hour infusion every 3 weeks. For non-small cell lung cancer, the recommended dose is 75 mg/m² IV as a continuous 1-hour infusion every 3 weeks. The optimal dosing schedule for docetaxel in gynecologic cancers is presently undefined. A 100-mg/m² dose administered as a 1-hour infusion every 3 weeks has been used in phase II trials. Other tolerable docetaxel dose schedules that have been identified in phase I studies are: 50 mg/m²/day on days 1 and 8 every 3 weeks; 70 to 90 mg/m² by 24-hour continuous IV infusion every 3 weeks; 80 to 100 mg/m² by 6-hour infusion every 3 weeks; 14 mg/m²/day for 5 days by 1-hour infusion every 21 days (220); and 30 to 35 mg/m² weekly (221,222). Docetaxel has been administered in combination with cisplatin using the following schedule: docetaxel 85 to 100 mg/m² as a 1-hour IV infusion followed (3 hours after completion) by cisplatin 75 mg/m² as a 3-hour IV infusion, with cycles being repeated every 3 weeks (223).

A number of clinical trials have explored the use of docetaxel given weekly in doses of 30 to 40 mg/m² (224–234). Weekly schedules have a different toxicity profile, with myelosuppression being less prominent, but fatigue becoming the dose-limiting side effects. Nail changes and excessive lacrimation are also more common. The response rates and dose intensities observed have been similar to those seen with the every-3-weeks schedule.

The docetaxel dose should be reduced for patients with moderate liver impairment (see Special Precautions section below).

Side Effects and Toxicities

The major dose-limiting toxicity of docetaxel is neutropenia, which is noncumulative and generally resolves within 7 to 8 days. The combined results of early phase II studies of docetaxel (without steroid premedication) in ovarian cancer revealed that at a dose level of 100 mg/m² every 3 weeks, greater than 90% of patients developed grades 3 to 4 neutropenia, with febrile neutropenia occurring in 8% to 44% of patients (235). The incidence of other grade 3 to 4 toxicities was stomatitis in 0% to 5%, diarrhea in 6% to 20%, dermatitis in 4% to 8%, acute hypersensitivity reactions 7% to 12%, and fluid retention in 8% to 12%. Other docetaxel-induced side effects include alopecia, anemia, neurosensory effects (paresthesia, dysesthesia, pain), and asthenia (220).

In early phase II studies, slow-onset (i.e., after 3 to 5 courses), cumulative fluid retention leading to peripheral or generalized edema with possible development of pleural effusion and/or ascites was a common dose-limiting toxicity. However, a 5-day premedication regimen with corticosteroids, starting the day before docetaxel administration, significantly reduces this side effect. In a retrospective analysis, severe fluid retention occurred in 20% of patients who received no premedication compared with 5% of patients who received steroid prophylaxis. Additionally, the percentage of patients who discontinued treatment secondary to fluid retention was reduced from 32% to 2% ($p < .00001$) with the use of a 5-day corticosteroid regimen (220). Steroid prophylaxis also reduces the incidence and severity of dermatologic side effects and hypersensitivity reactions.

The spectrum of docetaxel-induced hypersensitivity reactions is less severe than that associated with paclitaxel. In the absence of prophylactic medication, mild hypersensitivity reaction as characterized by flushing, rash, and pruritus occurs in approximately 5% of docetaxel administrations. Moderate reactions with dyspnea and/or slight hypertension occur in 8% of treatments, and severe reactions (with bronchospasm, angioedema,

and/or severe hypertension) occur in less than 2% of docetaxel administrations (236). Initial symptoms of hypersensitivity to docetaxel therapy generally occur within minutes of the start of the first or second course of docetaxel and resolve rapidly with interruption of the infusion. Patients can be successfully rechallenged with docetaxel therapy following medication with corticosteroids, antihistamines, and H₂-agonists.

Dermatologic toxicities typically appear as maculopapular eruptions and desquamation generally localized to the extremities. Nail changes, including onycholysis, may also occur. Skin changes are largely self-limiting and may be alleviated with glycerin/chlorhexidine ointment or oral pyridoxine. This side effect can often be prevented with prophylactic oral steroids and H₁- and H₂-agonists (237). Recurrent skin toxicity refractory to oral prophylactic medication and pyridoxine therapy may respond to local hypothermia during docetaxel administration (238).

Special Precautions

Patients with impaired liver function have a significant reduction in docetaxel clearance and an increased risk of life-threatening side effects. Analysis of the overall safety database revealed that patients with moderately impaired liver function (defined as transaminase levels more than 1.5 times the upper limit of normal and alkaline phosphatase more than 2.5 times the upper limit of normal) have a 27% reduction in docetaxel clearance and a 38% increase in the area under the concentration-time curve (220). When compared with patients with normal liver function, patients with at least moderately impaired liver function had a significantly greater incidence of febrile neutropenia (40% vs. 16%) and toxic death (20% vs. 1.4%). Grades 3 to 4 nausea/vomiting, stomatitis, and thrombocytopenia were also increased in patients with impaired liver function (220).

The recommended docetaxel dose level for a patient with moderate hepatic impairment (defined as transaminases between 1.5 and 3.5 times the upper limit of normal and an alkaline phosphatase between 2.5 and 6.0 times the upper limit of normal) is 75 mg/m² over 1 hour. No safe docetaxel dose can be recommended for patients with greater than moderate liver impairment (239).

Special Applications

Verschraegen and colleagues (240) published preliminary evidence that patients with ovarian cancer may respond to docetaxel even though they have had progression of their disease on paclitaxel. They noted a partial response rate of 37.5% in 8 eligible patients. A phase II study conducted by the GOG of 60 patients with paclitaxel-resistant ovarian and peritoneal carcinoma observed responses in 22.4% of patients, with 5.2% achieving complete response and 17.2% achieving partial response (at a dose of 100 mg/m² IV over 1 hour every 21 days) (241). However, the 75% incidence of grade 4 neutropenia in this study suggests that further study is needed to determine the appropriate dose and schedule.

Doxorubicin

Chemistry

Doxorubicin (Adriamycin), a primary agent in the treatment of metastatic endometrial cancer and advanced ovarian cancer, is an anthracycline antibiotic obtained from *Streptomyces peuceitii* var. *caesius*. It has a molecular weight of 580. The doxorubicin structure includes a water-soluble basic reducing amino sugar, daunosamine, linked by a glycosidic bond to carbon atom number 7 on the D-ring of the water-insoluble chromophore aglycone, adrimycinone.

Structural changes in the side groups of doxorubicin alter anti-tumor potency and pharmacokinetic properties. The aglycone is inactive, and modifications in the amino sugar substituents can also alter antitumor or toxic potency (242).

In DNA, the amino sugar projects into the minor groove and can interact electrostatically with negatively charged phosphate groups in the DNA strand to stabilize the aglycone moiety. Doxorubicin can also form complexes with iron or copper by means of the hydroquinone moieties (243). Metal-iron doxorubicin complexes may contribute to cardiotoxicity by enhancing redox cycling of the quinone moiety to produce membrane-damaging oxygen free radicals (244).

Doxorubicin hydrochloride is freely soluble in water, slightly soluble in normal saline, and very slightly soluble in alcohol.

Doxorubicin also is commercially available in a polyethylene glycol (PEG)-coated (pegylated, Stealth) liposomal form (see Liposomal Encapsulated Doxorubicin section below).

Mechanisms of Action

DNA Binding. The anthracyclines, including doxorubicin, probably have several modes of action. The anthracycline portion of the molecule appears to intercalate between stacked nucleotide pairs in the DNA helix by means of P-P-type bonds (245). The drug may also bind ionically around certain base pairs of DNA (adlination). The overall effect of this is interference with nucleic acid synthesis, specifically an inhibition of DNA synthesis (246). However, preribosomal RNA synthesis is also affected by the drug binding to DNA, preventing DNA-directed RNA and DNA transcription (247).

Mechanisms other than intercalation may also contribute to the antitumor effect of the doxorubicin molecule. The contribution of alkylation to antitumor effects has not been established.

Free-Radical Formation. Oxygen free-radical intermediates containing an unpaired electron can be formed by doxorubicin. This can react rapidly with oxygen to form superoxide, and with hydrogen peroxide, highly reactive hydroxyl radicals can form. These radicals damage membrane lipids by peroxidation, break DNA strands by attacking ribose-phosphate bonds, and directly oxidize purine or pyrimidine bases, thiols, and amines (244,248). Free-radical mechanisms have most often been associated with cardiotoxicity.

Doxorubicin appears to be active in all phases of the cell cycle, and although maximally cytotoxic in S phase, it is not phase specific (249). Cells exposed to lethal doxorubicin concentrations in G₁ can proceed through S phase but are then blocked and die in G₂. Higher concentrations can also produce an S-phase blockade (250).

Inhibition of DNA Topoisomerase II. Topoisomerases are enzymes capable of covalent binding to DNA, forming transient breaks in one strand (TOPO-I) or 2 strands (TOPO-II). This activity is highly phase dependent for G₂, and in the case of TOPO-II, normally mediates strand passage to facilitate DNA condensation or decondensation (251). Doxorubicin and other DNA intercalators inhibit the strand-passing activity of TOPO-II by increasing and stabilizing the initial enzyme-DNA (cleavable) complexes. This leads to protein-linked DNA double-strand breaks that are roughly proportional to the cytotoxic potency of the drug *in vitro* (252).

Drug Disposition

Doxorubicin pharmacokinetics is usually described using a 2-compartment or 3-compartment open model. The drug is rapidly distributed in body tissues, and approximately 75% of the drug is bound to plasma proteins, principally albumin (253). In the blood, the free doxorubicin fraction depends on the hematocrit, with more free drug being available in patients with reduced hematocrit (254). The avid binding to DNA is believed to explain the prolonged terminal elimination half-life of 30 to 40 hours, the large apparent volume of distribution of up to 28 L/kg, and the incomplete (50%) total recovery of drug in urine,

bile, and feces (255). Human tissues with high drug concentrations (in descending order) include liver, lymph nodes, muscle, bone marrow, fat, and skin (256). The drug does not distribute into the central nervous system.

There is a significant distribution of doxorubicin into human breast milk (257). Doxorubicin levels of 0.24 μM and 0.2 μM of doxorubicinol have been measured in human milk. They produce cumulative AUCs in breast milk of 9.9 and 16.5 $\mu\text{M} \cdot \text{hour}$, respectively. Both of these values were greater than concurrent plasma AUC values. However, doxorubicin does not appear consistently to pass the placenta. Except for one study reporting low drug levels in placental blood of 0.78 to 1.19 nmol/g and no drug in cord blood plasma, several other trials detected no drug in amniotic fluid after doxorubicin administration to pregnant patients (258–260).

Doxorubicin is extensively metabolized and eliminated primarily as glucuronide conjugates of the parent aglycone or its hydroxylated congener, doxorubicinol (255,261). The conjugated metabolites are exclusively excreted in the bile and feces. Overall, biliary excretion accounts for approximately 40% of an administered dose (262). Approximately 42% of the biliary drug is parent doxorubicin, 22% is doxorubicinol, and 36% is other metabolites (262). Only 5% to 10% of the administered drug is excreted in the urine as doxorubicin (40%), doxorubicinol (29%), and other metabolites (31%).

In liver disease, patients with cholestasis have delayed doxorubicin clearance and experience exaggerated toxic reactions from standard doses (263). However, hepatoma patients with cirrhosis or simple hepatocellular enzyme elevation appear to have normal doxorubicin clearance and toxic effects from standard doses (264). Although obesity reduces clearance of doxorubicin in adult cancer patients (265), there were no differences in doxorubicin toxicity between normal, mildly obese, and obese patients.

There is some evidence that repeated doxorubicin dosing alters pharmacokinetics (266,267). In these reports, doxorubicin levels were lower after repeated dosing, which suggests increased drug clearance. However, because neither toxicity nor response rates are altered, the clinical significance of these observations has not been established. Age may also be a factor. In one trial, the highest clearances of doxorubicin were observed in the younger patients (268). These observations suggest that higher peak doxorubicin levels may be achieved in older patients.

The hepatic extraction ratio for doxorubicin in humans is 0.45 to 0.50, and systemic drug levels are approximately 25% lower with intraarterial administration compared with IV dosing (269). Several studies have shown that the pharmacokinetics of intraarterial drug is similar to that of IV doses (256,270). The relatively low hepatic extraction rate and similar overall disposition patterns provide little pharmacokinetic rationale for intraarterial administration as a means of localizing doxorubicin effects to the liver (271).

Administration and Dosage

Short IV push infusions and IV bolus injections have been used with doxorubicin. A slow IV push over several minutes, with constant monitoring of the patient and blood return, can help minimize the chance of serious tissue damage from extravasation. A 5- to 10-mL flush of normal saline or D₅W before and after administration is strongly recommended to test vein patency and flush any remaining drug from the tubing. Alternatively, injection into the side port of a running IV infusion has also been recommended. The patient should be asked to report immediately any change in sensation during the administration. Old venipuncture sites or infusion sites previously used for administering blood, antibiotics, or other medications should not be used to administer doxorubicin. Heparin locks (unless recently inserted) are not recommended because the drug is chemically incompatible with sodium heparin.

Table 14.2 Intravenous Dosing Guidelines for Doxorubicin

Dose (mg/m ²) ^a	Intravenous Method	Schedule	Average Cumulative Tolerable Dose ^c (mg/m ²)
60–75 ^b	Bolus	Every 3 wk	550
30	Bolus	3 successive days, every 3 wk	550
20	Bolus	Weekly	750
60	96-hr infusion	Every 3–4 wk	1,000

^aLower doses should be administered to patients with hepatobiliary dysfunction and for poor bone marrow reserve or performance status.

^bAllows for greater dose intensity in breast cancer.

^cRepresents average total cumulative dose tolerated without clinical evidence of doxorubicin cardiotoxicity.

Prolonged infusions increase the incidence and severity of stomatitis and dermatologic reactions. Administration through tunneled central venous catheters or indwelling vascular access ports is mandatory for all prolonged infusions. Careful patient and site monitoring are required because doxorubicin extravasation from central vascular access devices can occur.

Numerous dosing schedules have been reported. The individual doxorubicin dose depends on clinical variables, including the cumulative dose administered to date and the potential for interaction with other drugs or radiation (Table 14.2). As a single agent, doses of 60 to 75 mg/m² as a single IV injection have been used and repeated no more often than every 3 weeks. An alternative scheme uses 20 to 30 mg/m² given daily for 3 consecutive days and repeated in 3 weeks (272). When used in combination therapy, the most commonly used dosage is 40 to 60 mg/m² given as a single IV injection every 21 to 28 days.

Both the dose and rate of dosing (dose intensity) can have therapeutic impacts for different agents and tumors (273). Clinical studies with doxorubicin show that greater dose intensity is associated with enhanced response rates in breast cancer (274). The doses compared in this trial were 70 mg/m² every 21 days for 8 cycles versus 35 mg/m² every 21 days for 16 cycles.

Dose adjustments are required in a number of clinical settings (Table 14.3), specifically in the case of hyperbilirubinemia. A 50% dose reduction is indicated if plasma bilirubin concentration is 1.2 to 3.0 mg/dL, and the dose must be reduced by 75% if plasma bilirubin concentration reaches 3.1 to 5.0 mg/dL.

Side Effects and Toxicities

The single acute dose-limiting toxicity for doxorubicin is bone marrow suppression. The most commonly seen dose-limiting toxicity is leukopenia, with a nadir at 10 to 14 days. Other hematologic toxicities, such as anemia and thrombocytopenia, have been reported, but they are rare and generally less severe. Recovery from myelosuppression is usually prompt, with resolution often within about 1 week after the nadir.

Doxorubicin is known to produce local skin and deep-tissue damage at the site of inadvertent extravasations (275,276). Ulcers result in 33% of extravasations. The lesions undergo a slow, indolent expansion and occasionally involve tendons and other deep structures. They characteristically do not heal and are associated with prolonged local drug retention (277). Reilly and colleagues (275) recommend early surgical debridement, with skin grafting and tendon repair for serious infiltrations. Numerous pharmacologic antidotes have been evaluated, but few have demonstrated unequivocal clinical efficacy. The application of cold, topical dimethylsulfoxide is recommended (278).

Table 14.3 Modifications of Doxorubicin Doses

Condition	Recommended Dose Modification
Prior doxorubicin	Limit total cumulative lifetime dose (by IV bolus) to 550 mg/m ² (285)
Prior chest Radiation therapy	Reduce total dose limit to 300–350 mg/m ²
Obesity	Base dose on ideal body weight (265)
Heptabillary dysfunction	Reduce dose for elevated serum bilirubin (give 50% of dose for serum bilirubin of 1.2–1.9 µg/dL, and give 25% of dose for serum bilirubin ≥ 3.0 mg/dL (282) Use indocyanine green disappearance rate as an Indicator of doxorubicin clearance
Infusion method	Greater cumulative (total) dose may be afforded by weekly bolus doses or continuous (96-hr) infusions ^a (Legha, 1982)

Note: Average safe cumulative doxorubicin dose is 750 mg/m² using standard infusion schedules.

^aAverage safe cumulative doxorubicin dose is 1,000 mg/m² when administered with a 96-hour infusion schedule.

Cardiac consequences from the drug have included acute effects, such as a rare pericarditis-myocarditis syndrome or electrophysiologic aberrations, and a total-dose-related cardiomyopathy (279,280). Nonspecific electrocardiographic changes during infusion or immediately afterward may be seen. These include T-wave flattening, ST depression, supraventricular tachyarrhythmias, and extra systolic contractions (281). These conduction abnormalities are generally transient, not associated with severe morbidity, and do not require dose modification.

Cardiomyopathy from doxorubicin is dose related. It presents initially as a clinical syndrome identical to classic congestive heart failure. It is usually irreversible, but symptoms can be managed with standard medical therapy involving digitalis, glycosides, and diuretics. Potential risk factors for doxorubicin cardiotoxicity include cumulative doses greater than 550 mg/m², prior mediastinal irradiation (≥20 Gy), age greater than 70 years, and preexisting cardiovascular diseases, such as prior myocardial infarction or long-standing hypertension (282). Anthracycline-induced cardiomyopathy can also occur 4 to 20 years after the drug is stopped at standard dose limits (283). The administration of anthracyclines incorporated into liposomes is one method that may significantly reduce the risk of cardiac toxicity (see Liposomal Encapsulated Doxorubicin section below) (284).

At total doses under 500 mg/m², the incidence of cardiomyopathy is less than 1%; between 501 and 600 mg/m², it is 11%; and the incidence is 30% for doses above 600 mg/m². In a retrospective cardiotoxicity study of 4,018 patient records, Von Hoff and associates (285) described an overall incidence of 2.2% for doxorubicin-induced congestive heart failure. In this analysis, there was no influence of performance status, sex, race, and tumor type on the incidence of cardiomyopathy. However, elderly patients were at greater risk even after adjustment for the normally decreased cardiac function in this group. The major determinants were the dose, the schedule of administration, and the age of the patient. A weekly doxorubicin dosing schedule was associated with significantly less congestive heart failure than an every-3-week dosing schedule. Continuous IV infusions over 96 hours also can significantly lessen doxorubicin cardiotoxicity (286).

Dexrazoxane (Zinecard) is a chemoprotective agent with an FDA-approved indication for reducing doxorubicin-associated cardiomyopathy in women with metastatic breast cancer who have received a cumulative doxorubicin dose of ≥300 mg/m² and

who, in their physician's opinion, would benefit from further doxorubicin therapy (see Modulating Agents section below).

There is evidence that doxorubicin is a radiosensitizing or "radiomimetic" agent and can cause reactivation of tissue reactions in areas previously irradiated (287,288). Radiation recall reactions have also been reported in areas of previous drug infiltration. A particularly sensitive area for serious recall toxicity is the esophagus (289).

Other toxic effects are observed in rapidly proliferating normal tissues. These include marked alopecia in all hairy body areas. Stomatitis may occur at high doses and is more pronounced when the drug is given on consecutive days. It generally begins in the sublingual and lateral tongue regions as a burning sensation with noticeable erythema. The initial inflammation typically progresses to ulceration after a few days. Anal fissures or proctitis have been rarely reported. Nausea and vomiting are common but of moderate intensity. Diarrhea is rare with consecutive daily dosing, and the emetic effects are generally limited to the first day of treatment. Hyperpigmentation of the skin, especially the nail beds, may occur. Extravasations of doxorubicin are known to cause severe ulceration and soft-tissue necrosis (275,276). Vein patency should be assured before injection and constantly monitored during administration.

As discussed later in this chapter, pegylated liposomal encapsulation dramatically alters the pharmacokinetic profile of doxorubicin and, hence, the drug's toxicity profile.

Drug Interactions

Doxorubicin is believed to interact with numerous other drugs. Most of these effects have been described only in experimental systems, and their clinical significance is, therefore, unknown. However, several potentially significant interactions have been described in cancer patients. Altered doxorubicin disposition is postulated with α -interferon, and substantial doxorubicin dose reductions are required (290). The combination of doxorubicin with H_2 -antihistamines, such as ranitidine or cimetidine, may also increase toxicities significantly and necessitate drug dose reduction.

Special Applications

Doxorubicin has been investigationally administered intrapleurally to patients with malignant pleural effusions (291). Doses of 30 mg were diluted in 20 mL of saline and administered by paracentesis needle as a bolus. Eight of 11 patients responded to doxorubicin, including one complete response. This response rate was superior to nitrogen mustard or tetracycline. Toxicity included pain or fever in 20% of patients and nausea or vomiting in 45% of patients. No alopecia or hematologic toxicity was reported. Markman and colleagues (292) combined doxorubicin (3 mg) with cytarabine (61 mg) and cisplatin (100 mg/m²) in the treatment of 7 cancer patients with malignant pleural effusions. Two ovarian cancer patients responded, and no significant systemic toxicities were reported. All injections were given in 250 mL of saline, and aggressive hydration was given to counteract cisplatin nephrotoxicity.

Etoposide

Chemistry

Intravenous etoposide (VP-16) is used commonly in combination chemotherapy regimens for the treatment of patients with germ-cell tumors of the ovary (206). Oral etoposide has activity as a salvage agent for refractory or recurrent ovarian cancer (293). It is a semisynthetic epipodophyllotoxin derived from the root of *Podophyllum* (the May apple plant, or mandrake). The chemical name is demethylepipodophyllotoxin 9-[4,6-O-(R)-ethylidene- β -D-glucopyranoside]. Etoposide has the molecular formula of $C_{29}H_{32}O_{13}$ and a molecular weight of 588.58. It is

highly soluble in methanol and chloroform, slightly soluble in ethanol, and sparingly soluble in water. Because of poor water solubility, the commercial drug is dissolved in an ethanol-based cosolvent system.

Etoposide was originally synthesized from *P. embodi* (294). Structure-activity studies show that the hydroxyl group at the C-4' position is required for activity and that alterations at this site can dramatically affect activity.

Mechanism of Action

There is marked schedule dependence for etoposide cell killing, and cytotoxic effects are maximal in G_2 phase (295). There is also some activity against cells in late S phase, and the drug can halt cell cycle traverse at the S- G_2 interphase (296).

Etoposide produces protein-linked DNA strand breaks by inhibiting DNA TOPO-II enzymes (297). This normal mammalian enzyme mediates double-strand-passing activities in G_2 phase to condense or decondense supercoiled DNA (298). Drug-induced inhibition of TOPO-II is an energy-dependent process that is influenced by dose and duration of exposure.

Etoposide does not bind directly to DNA, but rather stabilizes a transition form of the DNA-TOPO-II complex (297). The number of single and double DNA strand breaks reflects the cytotoxic dose-response curve (299). Etoposide and intercalative drugs, such as doxorubicin, "poison" TOPO-II enzymes by stabilizing an otherwise transient form of TOPO-II covalently linked with DNA (252). Normal TOPO-II strand-passing activity is thereby blocked, and cell progression out of G_2 phase is halted (251,300). The production of cytotoxicity by etoposide may ultimately involve chromosomal breaks characterized as sister chromatid exchanges (301).

Another postulated etoposide mechanism involves microsomal activation to reactive intermediates capable of generating oxygen free radicals (299). Nucleoside transport is also inhibited at high drug concentrations, but whether this makes a major contribution to the antitumor effect is unknown (302).

Drug Disposition

A 2-compartment open pharmacokinetic model appears to describe adequately etoposide disposition in cancer patients (303). The terminal half-life of the drug appears to be approximately 7 hours and is independent of the dose, route, or method of administration (304). Renal excretion appears to account for approximately 30% of overall drug elimination. Approximately 42% to 66% of radiolabeled drug is recovered in the urine, of which less than half is parent etoposide.

With standard doses of etoposide, no drug is detectable in the cerebrospinal fluid (CSF), and even after doses of 400 to 800 mg/m², CSF levels were less than 2% of concurrent plasma levels (305). Despite the low distribution of drug into the CSF, mean levels of 1.4 μ g/g (range, undetectable to 5.9 μ g/g) have been measured in brain tumor tissue (306). The drug also distributes into myometrial carcinoma and normal myometrium, achieving levels 50% of those in the blood (307).

Biliary secretion of parent drug accounts for 2% or less of the dose, although fecal recovery of drug and metabolites is variable, ranging from 1.5% to 16.3% (308). However, patients with obstructive jaundice excrete a larger fraction of the dose in urine (46%) than do unaffected patients (35%), which suggests that there is a slight decrease in hepatic drug metabolism with a commensurate increase in renal clearance (305).

The plasma protein binding of etoposide is normally high, averaging 95% in typical patients (309). The free (unbound) fraction of etoposide can vary from 6% to 37% among patients. Patients with increased bilirubin or decreased albumin may have an increase in the free fraction even though systemic clearance is unaltered (309). Myelosuppression may also be commensurately increased in these patients. Other conditions that may decrease

etoposide clearance include prior cisplatin therapy, obesity, and elevated alkaline phosphatase levels (310).

The absolute oral bioavailability of etoposide gelatin capsules ranges from 25% to 74%, with a mean of 48% (311). Some patients experience a 30% change in overall bioavailability (both increased and decreased) with repeat dosing. Neither food nor other chemotherapeutic agents appear to alter etoposide absorption (312). Wide variations in peak levels and AUC values were also described in this trial.

Administration and Dosage

Etoposide must be diluted prior to use with either 0.5% dextrose or 0.9% sodium chloride to give a final concentration of 0.2 to 0.4 mg/mL. Etoposide should be given by IV infusion over a 30- to 60-minute period. Severe hypotension may occur if the drug is given too rapidly. Although not a vesicant, extravasation of the drug should be avoided (313). Examine all solutions for fine precipitates; mix before use. Precipitation may occur if the solution is prepared at the concentration of 0.4 mg/mL. Continuous infusions of etoposide have been used as a means of enhancing efficacy because of its phase-specific mode of antitumor action. Most infusions have used 5-day courses, although 72-hour infusions have also been employed (314,315).

Oral administration of etoposide capsules may be useful if patient compliance is high, and low-emetogenic drug regimens are used. The capsules may be taken all at once to achieve the desired dose. Neither food nor other chemotherapeutic drugs appear to alter oral absorption of the drug (312). The GOG has investigated multiple trials of oral etoposide at various dosing regimens. Based on a cumulative review of these trials and schedules, it was found to be active in platinum-resistant ovarian cancer patients (overall response rate 26.8%; 7.3% clinical complete remission rate) and in platinum-sensitive patients (overall response rate 34.1%; 14.6% clinical complete remission rate) (314). One of these trials that demonstrated activity used an oral etoposide dosing schedule of 50 mg/m²/day for 21 days every 28 days with dose escalation to 60 mg/m²/day when feasible (316). Studies using similar oral etoposide dosing schedules in patients with cervical cancer and endometrial cancer failed to show significant activity in these tumor types (317–319).

The variety of doses and schedules that have been used with etoposide are presented in Table 14.4. General principles of

dosing include more frequent administration to take advantage of cell cycle-dependent cytotoxicity, an approximate doubling of oral doses due to 50% bioavailability for the gelatin capsules, and significant dose reductions for combinations of etoposide with other myelosuppressive drugs or for patients with poor bone marrow reserve or poor performance status. In general, etoposide doses can be repeated every 3 to 4 weeks depending on the leukocyte count. A pharmacokinetic study in patients with obstructive jaundice showed that no significant dose reductions are needed if renal function is normal (320).

Side Effects and Toxicities

Side effects and toxicities for oral and IV administration of etoposide as a single agent are similar. The principal toxicity of etoposide is dose-related and dose-limiting bone marrow suppression. Leukopenia and thrombocytopenia can occur, but leukopenia consistently predominates, with a nadir at approximately 16 days and with recovery usually beginning by days 20 to 22.

Gastrointestinal complaints of nausea, vomiting, or anorexia are usually minor and are more frequent with the oral preparations (321). Other adverse effects include alopecia in 20% to 90% of patients, headache, fever, and hypotension (322). Severe hypotension can occur if the drug is infused too rapidly (<30 minutes) (308). Stomatitis has been infrequently reported. Rare instances of generalized allergic reactions and anaphylaxis have occurred (323). A few episodes of cardiotoxicity, including myocardial infarction and congestive heart failure, have been described (324). Immune suppression appears to be minimal with this drug (322). Bronchospasm with severe wheezing has been rarely observed and has usually been responsive to antihistamines and glucocorticosteroids. Chemical phlebitis also has been associated with etoposide, although the reaction is most likely related to solubilizers in the diluent. Diluted solutions of etoposide are not vesicants. For inadvertent extravasations of highly concentrated etoposide solution, hyaluronidase may be effective (325).

Neurotoxicity has been rarely reported with etoposide. This has consisted of somnolence and fatigue in 3% of patients and peripheral neuropathy in less than 1% of patients. However, the drug may exacerbate preexisting neuropathy caused by vincristine (326). Predisposing factors included advanced age, impaired nutritional status, and poor performance status. Degradation of myelin lamellae has been observed in affected nerves.

Table 14.4 Intravenous and Oral Dosing Schedules for Etoposide

Administration Method	Dose		Repeat Dosing Interval (wk)	Clinical Application
	mg/m ² /day	Days		
Short single-dose IV infusion	200–250	1	7	Single agent, small-cell lung cancer
Short multiple-dose IV infusion	100	1–5	3–4	Testicular cancer
	100	1, 3, 5	3–4	With other drugs
	45	1–7	3	Phase I
Continuous IV infusion	125	1–5	4	Phase I, single agent
	30	1–5	4	With cisplatin in advanced cancer
	80	1–5	4	Phase I, good-risk patients
	50	1–5	4	Poor-risk patients
	125	1–3	4	Adult patients with advanced cancer (240)
	500	1 (24-hr)	3	Small-cell lung cancer
Oral	160	1–5	3–4	Small-cell lung cancer
	50	1–21	4	Ovarian cancer (243)

Special Applications

Despite preclinical data showing peritonitis with IP injections, combinations of etoposide and cisplatin have been administered safely by the IP route. Barakat et al. (327) performed a phase II study of 3 courses of IP cisplatin 100 mg/m² plus etoposide 200 mg/m² as consolidation therapy in patients with stages II to IV epithelial ovarian cancer with negative second-look surgeries. When compared with a similar group of contemporaneous patients who did not receive consolidation therapy, the disease-free survival distribution between the 2 groups (using the log-rank test) was found to be significant ($p = 0.03$) in favor of consolidation therapy (327). European researchers have used a combination of etoposide 350 mg/m² IP followed by cisplatin 200 mg/m² IP with IV sodium thiosulfate (4 g/m² bolus followed by 12 g/m² over 6 hours) protection every 4 weeks for 4 to 6 cycles in ovarian cancer patients with either no residual disease or minimal residual disease at second-look surgery. The regimen was fairly well tolerated, although there was one study-related patient death from a bowel perforation and resulting complications. Other major clinical complications were nausea, vomiting, and the formation of intra-abdominal adhesions. Grade 3 to 4 leukopenia and thrombocytopenia occurred in 30% and 6% of cycles, respectively (328).

Etoposide in combination with other chemotherapeutic agents and autologous stem-cell rescue is often used in salvage therapy for germ-cell tumors or metastatic trophoblastic disease. Two commonly used regimens are bleomycin, etoposide, and cisplatin (BEP); and ifosfamide, carboplatin, and etoposide (ICE) (329,330).

5-Fluorouracil and Floxuridine

Chemistry

5-Fluorouracil (5-FU) is a fluorinated pyrimidine differing from the normal DNA substrate, uracil, by a fluorinated number 5 carbon (chemically, 5-fluoro-2,4(1H,3H)-pyrimidinedione). 5-FU has activity as a second-line agent in advanced ovarian and cervical cancers and, in combination with cisplatin, is used as an adjunct to radiation therapy in women with locally advanced cervical cancer. Floxuridine (FUDR) is highly similar to its prodrug, 5-FU. The discussion of FUDR in this chapter will be limited to its special application as an IP-administered agent for salvage therapy for ovarian cancer. 5-FU is light sensitive and precipitates at low temperatures or, occasionally, with prolonged standing at room temperature. It has the molecular formula of C₄H₃FN₂O₂ and a molecular weight of 130.08.

Mechanism of Action

5-FU acts as a false pyrimidine or antimetabolite ultimately to inhibit the formation of the DNA-specific nucleoside base thymidine. There are at least 3 mechanisms of action: inhibition of thymidylate synthase by 5-fluoro-21-deoxyuridine-5'-monophosphate (FdUMP), the active metabolite of 5-FU; incorporation of 5-fluorouridine triphosphate (FUTP) into cellular RNA; and incorporation of FUTP into cellular DNA (331). 5-FU is a cell cycle phase-specific agent with cytotoxic effects seen maximally in S phase.

Drug Disposition

There is disagreement over whether 5-FU is eliminated by a 2-compartment or 3-compartment model (2,332,333). Fraile and associates (334) demonstrated that plasma levels of 5-FU after oral administration are quite erratic. Schaaf and colleagues (335) documented that the pharmacokinetic characteristics of 5-FU are nonlinear. Doubling of the dose was accompanied by a decrease in nonrenal clearance. The half-life from the high dose

was twice as long as that for the low dose of 5-FU. Their data were compatible with a product-inhibition model. Yoshida and coworkers (336) found positive correlations between the dose and serum steady-state levels (C_{ss}) and areas under the concentration-time curves (AUC). Patients who developed toxic reactions had greater C_{ss} s and AUCs. However, there were no correlations between serum levels and patient response to therapy.

5-FU and FUDR are extensively metabolized in the liver (hepatic metabolism can detoxify up to 80% of the total dose). However, there is no absolute documentation that patients with impaired liver function require dose reductions of 5-FU (337); however, patients should be monitored as they may be at increased risk of toxicity. As much as 15% of a dose may be found intact in the urine by 6 hours, with 90% of this excreted in the first hour. Depressed renal function does not generally require dosage adjustment for 5-FU.

5-FU distributes to all areas of body water by simple diffusion. Significant quantities of the drug may enter the central nervous system, and after 15 mg/kg given IV, CSF levels of 6 to 8×10^{-6} M are obtained after 30 minutes. These levels persist for several hours and slowly subside. Although distribution to brain tissue is less rapid, abnormal areas, such as those with neoplasms, may more readily take up the drug.

5-FU achieves high and persistent levels in effusions after IV administration. Hepatic administration through the portal vein or artery also achieves high concentrations in the liver parenchyma and produces relatively low systemic levels.

Santini and colleagues (338) showed that therapeutic monitoring of 5-FU levels in patients with head and neck cancer can be used to improve the therapeutic index of the drug (i.e., less toxicity with maximal efficacy).

Administration and Dosage

Doses of 5-FU to be given by the IV push route do not require further dilution from the commercial solution. Vein patency should be assured before giving a dose, with a 5- to 10-mL flush of normal saline or D₅W and another flush after the dose to rinse the remaining drug from the tubing. For short infusions (<24 hour), the rate of administration is not critical, and the dose should be given at a rate compatible with the particular vein selected. The patient should be continuously monitored to guard against extravasation. Most doses can be conveniently given over 1 to 2 minutes in this fashion.

Continuous infusions (over 4 to 5 days) may maximize efficacy of this cycle-specific drug and lessen hematologic toxicity (339–341). Infusions of the drug may be added to a convenient volume of D₅W or normal saline, and each reconstituted daily dose can be administered over 24 hours. Commonly, the daily dose of the drug is added to 1 L, although volume is not critical.

Regimens reported for the use of 5-FU include the use of a loading dose, weekly IV bolus, continuous infusions over 4 to 5 days or over 6 weeks, and oral dosing. 5-FU may be administered intravenously as a bolus, rapid injection on a monthly (425 to 450 mg/m² IV on days 1 to 5 every 28 days) or a weekly schedule (500 to 600 mg/m² every week for 6 weeks, every 8 weeks), or continuous IV infusion (24-hour infusion 2,400 to 2,600 mg/m² every week; 96-hour infusion 800 to 1000 mg/m²/day; or 120-hour infusion 1,000 mg/m²/day on days 1 to 5 every 21 to 28 days) (79). Oral doses of up to 15 to 20 mg/kg/day for 5 to 8 days have been used (342). However, the efficacy of oral 5-FU has not been confirmed at this time (see Capecitabine section above for a discussion of the oral prodrug of 5-FU).

The loading dose scheme calls for one course of 400 to 500 mg/m² (12 mg/kg; maximum of 800 mg) daily for 5 days every 28 days given as a single daily bolus injection or as a 4-day continuous infusion. This is followed by a weekly maintenance regimen. Horton and coresearchers (343) and Jacobs

and coworkers (344), however, strongly associated the use of the loading dose with significant morbidity and occasional fatalities, and suggested that it offers no greater antitumor efficacy over a weekly bolus injection of 15 mg/kg given IV.

Maintenance of 5-FU dosing regimens include the following: 200 to 250 mg/m² (6 mg/kg) every other day for 4 days, repeated in 4 weeks (if toxicity has resolved); or 500 to 600 mg/m² (15 mg/kg), given IV weekly as a continuous infusion or bolus injection (with and without the loading dose).

By continuous infusion, higher daily doses have been successfully used, and many investigators have reported lessened hematologic toxicity and enhanced efficacy. Most of a dose is eliminated by the liver and the remainder by the kidney. Therefore, marked dysfunction in either system probably requires a dose reduction.

There are 2 commonly used dosing regimens for 5-FU combined with leucovorin: 370 mg/m²/day of 5-FU for 5 days plus leucovorin given as a continuous infusion of 500 mg/m²/day, beginning 24 hours before the first dose of 5-FU and continuing for 12 hours after completion of therapy; or 5-FU given at doses of 500 to 1,000 mg/m² every 2 weeks, preceded by calcium leucovorin at a dose of 20 mg/m² given as a 10-minute infusion (345,346).

Phase III studies performed by the GOG, SWOG, and Radiation Therapy Oncology Group have documented the efficacy of cisplatin/5-FU chemotherapy as an adjunct to radiation therapy in women with high-risk cervical cancer (47,184,347). The regimen used in the SWOG study was cisplatin 70 mg/m² by 2-hour IV infusion on day 1 of radiation followed by 5-FU 1,000 mg/m²/day by 96-hour continuous infusion on days 1 to 4 every 3 weeks for 4 cycles, with the first and second cycles given concurrently with radiation therapy (184). The addition of concurrent cisplatin-based therapy to radiation therapy significantly improved progression-free and overall survival in this study; however, no definitive study has compared cisplatin versus cisplatin/5-FU as an adjunct to radiation therapy for cervical cancer, and the relative importance of 5-FU remains to be addressed.

Side Effects and Toxicities

The most pronounced and dose-limiting toxic effects of 5-FU are on the normal, rapidly proliferating tissues of the bone marrow and the lining of the gastrointestinal tract. Some nausea and vomiting can be expected. These adverse effects may respond relatively well to antiemetic treatment. Stomatitis, however, is usually an early sign of impending severe toxicity that may become evident after 5 to 8 days of therapy. Symptoms include soreness, erythema, or ulceration of the oral cavity or dysphagia. Other reported gastrointestinal symptoms are diarrhea, proctitis, and esophagitis.

Leukopenia, primarily granulocytopenia, and thrombocytopenia occur with a nadir at 9 to 14 days for the granulocytes and 7 to 14 days for platelets. Patients who are poor candidates for 5-FU therapy are those with a total leukocyte count of 2,000/mm³ or less, or platelet count of 100,000/mm³ or less, or those with poor nutritional status at the outset of therapy.

Some degree of alopecia is expected, although hair regrowth has occurred even when successive doses are given. Partial loss of nails and hyperpigmentation of the nail beds and other body areas (e.g., face, hands) have been reported. These may resemble the hyperpigmentation seen in Addison's disease. A maculopapular rash may occur on the extremities and sometimes the trunk. The rash is usually reversible. Sunlight may initiate or heighten many dermatologic reactions to 5-FU.

PPEs have been reported with very long continuous infusion 5-FU (over several weeks). This has been reported in 42% to 82% of patients in various series. The syndrome is progressive and disrupts treatment (348). This has encouraged the development of prodrugs of 5-FU, such as 5'-deoxy-5-fluorouridine,

capecitabine, BOF-A2, ftorafur, UFT, and S-1 (349,350). Although there is no indicated treatment for PPE, the incidence has been reduced to a few percentage points by limiting 5-FU continuous infusion durations to 21 days with at least 1 additional week off drug. Possible therapies that are yet to be evaluated in clinical trials include DMSO, systemic corticosteroids, and pyridoxine (vitamin B₆) (349,351).

Hyperpigmentation over the veins used for 5-FU administration has been observed (352). In one instance, the veins remained patent, but there was marked darkening of the skin immediately over the vein.

5-FU may also cause an acute cerebellar syndrome that can persist beyond the period of actual treatment (353,354). Neurotoxicity may be evidenced by headache, minor visual disturbances, cerebellar ataxia, or all 3. This is a rare complication. The neurotoxic metabolite is probably fluorocitrate.

Cardiotoxicity is a rare but potentially serious toxicity attributable to 5-FU. The incidence of cardiotoxicity may vary from 1.2% to 18.0% of patients (355) and includes cases of myocardial infarction, angina, dysrhythmias, cardiogenic shock, sudden death, and electrocardiographic changes. The mechanism producing 5-FU-induced cardiotoxicity is unknown.

Special Precautions

5-FU should never be given to pregnant women. 5-FU may increase the cortisone requirement in patients who have had an adrenalectomy (e.g., for breast cancer), and consideration should be given to increased doses of cortisone for patients receiving 5-FU.

Because dihydropyrimidine dehydrogenase is the rate-limiting enzyme in the metabolism of 5-FU, patients with a familial deficiency of dihydropyrimidine dehydrogenase (familial pyrimidinemia) should not receive 5-FU. The administration of 5-FU to patients with this enzyme deficiency has led to severe toxicity and even death (356,357).

Accidental splashing of 5-FU on the skin or eyes of personnel should be treated with immediate irrigation with saline solution or water. There have been no long-term sequelae of these accidents (358).

Because of the alkaline nature of the drug, admixture with any acidic agents (amino acids, penicillin, multivitamins, insulin, tetracycline) represents a theoretic incompatibility.

Special Applications

FUDR, a closely related analog of 5-FU, has efficacy as a salvage agent when administered as an IP agent to stage III ovarian cancer patients with minimal residual disease (i.e., <1 cm) following second-look surgery. A SWOG study utilized IP FUDR (3 g/day for 3 days every 3 weeks for 6 courses) as a salvage regimen in this patient population and documented a median overall survival of 38 months (359). Additionally, 69% of study patients had not progressed 12 months after receiving IP FUDR. Because the majority of the IP FUDR dose is extracted during "first pass," it is relatively well tolerated, although grade 4, uncomplicated neutropenia was observed in 14% of patients (359). Because of the favorable 1-year progression-free survival in this study, a subsequent phase I to II trial was conducted by the SWOG (360). The researchers recommend that the regimen of IP FUDR + IP cisplatin (or IP FUDR with both platinum) be tested in a phase III trial in comparison to IP cisplatin (360).

Speyer and colleagues (361) investigated IP 5-FU in patients with ovarian and colon carcinomas. Using a Tenckhoff catheter, patients received repeated 36-hour courses of eight 2-L exchanges, each 4 hours long, or a 3- to 5-day course of single, daily 2-L instillations. 5-FU concentrations ranged from 10⁻⁶ M (130 µg/L) to 8 × 10⁻³ M (1 g/L).

The procedure was relatively well tolerated locally, although there were 2 instances of catheter-related bacterial peritonitis that were easily managed. Concentrations of 4×10^{-3} M for 36 hours caused mucositis, pancytopenia, and alopecia. The systemic toxicities were quite severe with the highest dose tested (8×10^{-3} M). Pharmacokinetic studies revealed first-order drug elimination, with an IP half-life of 72 to 112 minutes. Intraperitoneal drug levels were 300-fold greater than simultaneous plasma levels. Intraperitoneal 5-FU administration appears to produce high drug concentrations with minimal systemic toxicity. Objective responses were documented in 2 of 7 patients studied in this phase I investigation. The investigators recommended further IP 5-FU investigation at initial drug concentrations of 4×10^{-3} M (500 mg/L) for 36 hours (361).

Suhrland and Weisberger (362) used intracavitary 5-FU to manage malignant pleural effusions from carcinoma of the breast and lung tumors and to control malignant ascites from ovarian carcinoma. Approximately 38% of the patients responded to a single intracavitary dose of 2 to 3 g. For pericardial effusions, doses of 500 to 1,000 mg were used. Repeat dosing was not necessary. Patients with pleural effusions also tended to respond better than those with ascites. Although side effects were minimal in this study, some systemic toxicity was consistently produced.

Gemcitabine

Chemistry

Gemcitabine (Gemzar) is a relatively new chemotherapeutic agent that was approved by the FDA in 1995 for the treatment of patients with advanced pancreatic cancer based on an increase in survival and clinical benefit (improvement in pain and performance status). The combination of gemcitabine plus cisplatin also is FDA approved and is considered standard therapy for patients with advanced non-small cell lung cancer. Gemcitabine has demonstrated significant activity in advanced ovarian cancer patients and is active against refractory ovarian cancer and cervical cancer, as well as other solid tumors (363–367). Gemcitabine is a synthetic nucleoside analog with a structure that is highly similar to deoxycytidine and cytosine arabinoside (ara-C). Gemcitabine HCl is 2'-deoxy-2',2'-difluorocytidine monohydrochloride (β isomer). The empiric formula for gemcitabine is $C_8H_{11}F_2N_3O_4 \cdot HCl$ and the agent has a molecular weight of 299.66.

Mechanism of Action

Gemcitabine is a prodrug and undergoes multiple phosphorylations by deoxycytidine kinase at the intracellular level to form the active diphosphate and triphosphate metabolites. The triphosphate is incorporated into DNA as a fraudulent base pair. Following the insertion of gemcitabine, one additional deoxynucleotide is added to the end of the DNA chain before replication is terminated. This process is known as “masked chain termination” and prevents exonucleases from excising off the fraudulent base pair (368,369). The diphosphate inhibits ribonucleotide reductase and thereby depletes the deoxynucleotide pools that are necessary for DNA synthesis and repair (370). Inactivation of gemcitabine occurs when the drug is metabolized by cytidine deaminase (both intracellularly and extracellularly) to form difluorodeoxyuridine (371).

Drug Disposition

Following administration of gemcitabine 1,000 mg/m² by 30-minute IV infusion, the parent compound undergoes rapid clearance in a biphasic manner. The plasma half-life and clearance are dose, age, and gender dependent. Gemcitabine pharmacokinetics were evaluated in 353 patients with varied solid tumors using short infusions (<70 minutes) and long infusions

(70 to 285 minutes) at various total doses (500 to 3,600 mg/m²) (372). There is a three- to fourfold interpatient variability in pharmacokinetics. As noted above, gemcitabine is metabolized intracellularly by deoxycytidine kinase to form the active diphosphate and triphosphate metabolites. The drug is inactivated both intracellularly and extracellularly by cytidine deaminase to form difluorodeoxyuridine (dFdU). Of the administered gemcitabine dose, 99% is excreted in the urine either as the parent compound (<10%) or as dFdU (373,374).

Dutch researchers have performed a pharmacokinetic schedule-finding study of gemcitabine plus cisplatin. Gemcitabine 800 mg/m² was administered as a 30-minute infusion either 4 hours before, 24 hours before, 4 hours after, or 24 hours after administration of cisplatin 50 mg/m² by 1-hour IV infusion. Neither of the dosing schedules that used a 4-hour interval between drug administrations resulted in significant pharmacokinetic or pharmacologic differences. However, when gemcitabine was administered 24 hours before cisplatin, there was a twofold decrease in the plasma AUC of platinum. Furthermore, when the order of the drugs was reversed (i.e., cisplatin was administered 24 hours before gemcitabine), there was a 1.5-fold increase in the concentration-time product of the active triphosphate metabolite of gemcitabine within white blood cells. On the basis of these results, the investigators conducted a phase II study of the cisplatin/gemcitabine combination wherein cisplatin was administered 24 hours prior to gemcitabine (375).

Administration and Dosage

Gemcitabine should be diluted in 0.9% sodium chloride to a concentration of no greater than 40 mg/mL (higher drug concentrations may result in incomplete dissolution). Gemcitabine is generally administered as a 30-minute IV infusion at a dose of 1,000 mg/m²; infusion durations of greater than 60 minutes are associated with dose-limiting flu-like symptoms (376).

The standard dosing schedule used for treatment of pancreatic cancer is 1,000 mg/m² by 30-minute IV infusion once weekly for 7 weeks for cycle 1 followed by a 1-week rest and then 1,000 mg/m² once weekly for 3 weeks followed by a 1-week rest for subsequent cycles (377).

Multiple phase II studies of single-agent gemcitabine in refractory/recurrent ovarian cancer have used a dosing schedule of 800 to 1,250 mg/m² once weekly for 3 weeks followed by a week of rest; however, doses above 1,000 mg/m² may be associated with higher toxicity (364,366,378).

In vitro studies have shown synergism between gemcitabine and cisplatin in a variety of human cancer cell lines (379,380). It is believed that this synergism is primarily the result of increased platinum-DNA adduct formation (380). An increase in DNA-platinum adducts has also been demonstrated for the combination in the clinical arena (381). As noted (see Drug Disposition section above), the interval between cisplatin and gemcitabine administration can affect both pharmacokinetic and pharmacologic parameters (375). This combination appears to be especially promising for patients with advanced ovarian cancer. Several phase II studies have been conducted in previously untreated ovarian cancer patients using a dosing schedule of cisplatin (75 to 100 mg/m²) on day 1 followed by gemcitabine 1,250 mg/m² days 1 and 8 (363,382,383). Others have performed phase II studies of gemcitabine plus cisplatin for patients with relapsed ovarian cancer after prior platinum-based chemotherapy and have determined that cisplatin 30 mg/m² plus gemcitabine 600 to 750 mg/m² on days 1 and 8 every 21 days is an active and tolerable regimen that demonstrated activity in platinum-resistant patients (130,384).

A phase III study comparing 4 different carboplatin-based regimens with the standard regimen of carboplatin + paclitaxel for the first-line treatment of ovarian cancer showed very similar survival and progression-free survival for the

gemcitabine-containing arm, confirming the activity of gemcitabine but not demonstrating superiority over standard treatment.

Side Effects and Toxicities

Gemcitabine-induced toxicity is highly schedule dependent; small daily doses are associated with greater toxicity than large doses administered on a weekly basis (385). The dose, schedule, and duration of infusion of gemcitabine directly affect the toxicity profile (385). Infusion durations of more than 60 minutes are associated with increased myelosuppression and hepatic toxicity, whereas the administration of small daily doses results in dose-limiting flu-like symptoms (371,376). When gemcitabine is administered using the standard weekly dosing schedule, therapy is generally well tolerated and bone marrow suppression is the major dose-limiting toxicity.

Analysis of safety data from 22 completed clinical trials in which gemcitabine was administered on a weekly basis to 979 patients revealed that neutropenia was the most significant hematologic side effect. Six percent of patients experienced grade 4 neutropenia, and an additional 20% experienced grade 3 neutropenia. Grade 4 leukopenia was experienced by less than 1% of patients. Decreases in white blood cell counts were noncumulative, short-lived, and rarely resulted in complications. Only 6 of 979 patients (1.1%) developed severe infections, and no patient developed a life-threatening infection. Grades 3 and 4 anemia were experienced by 6.8% and 1.3% of patients, respectively, and only 2 of the 979 patients discontinued gemcitabine secondary to anemia. Grades 3 and 4 thrombocytopenia occurred in 4.1% and 1.1% of patients, respectively. Less than 1% of patients received platelet transfusions, and only 4 patients (0.4%) discontinued therapy on account of thrombocytopenia (385).

Gemcitabine is associated with a low incidence of hepatic toxicity. Grade 3 elevations in alkaline phosphatase, alanine aminotransferase (ALT), or aspartate aminotransferase (AST) occurred in less than 8% of patients. Grade 4 elevations in these liver enzymes occurred in 2% or less of patients. Grade 3 or 4 increases in bilirubin occurred in 1.8% and 0.8% of patients, respectively. It is noteworthy that one-third of patients in this study population had documented liver metastases (385).

Clinically significant renal toxicity rarely occurs with gemcitabine therapy. However, rare cases of hemolytic uremic syndrome have been reported with gemcitabine therapy. The incidence is believed to be approximately 0.6% (385,386).

Other nonhematologic toxicities reported in more than 5% of patients were nausea/vomiting (64.3% overall, 17.1% grade 3, 1.2% grade 4), fever (37.3% overall, 0.7% severe), edema (>20% of patients), flu-like symptoms (18.9%, 0.9% severe), cutaneous reactions (24.8%, 0.2% severe), alopecia (14.1%, 0.4% severe), diarrhea (12.1%, 0.7% severe), somnolence (9.1%, 0.9% severe), infection (8.7%, 1.1% severe), mucositis (8.4%, 0.2% severe), constipation (7.8%, 0.7% severe), and dyspnea (7.7%, 1.2% severe). Nausea and vomiting rarely were dose limiting, and only 2 (0.2%) patients discontinued gemcitabine therapy because of nausea. Fever was a fairly frequent toxicity and sometimes occurred in the absence of flu-like symptoms or infection. Subcutaneous edema, including peripheral edema and facial edema, occurred in a significant number of patients. Edema was generally mild to moderate in nature; few patients (0.6%) discontinued gemcitabine because of this side effect, and the edema resolved after drug discontinuation. Flu-like symptoms consisted of headache, back pain, chills, myalgia, asthenia, and anorexia and were generally short lived. Paracetamol was reported to provide relief to some patients. Cutaneous reactions consisted of erythema in mild cases (15.5%) and dry desquamation, vesiculation, and/or pruritus in moderate cases (9.1%). Only one patient developed severe cutaneous toxicity characterized as moist desquamation and ulceration. Dyspnea (with or without bronchospasm) occurs in

less than 10% of patients following gemcitabine administration. This toxicity generally occurs within a few hours of treatment and resolves within 6 hours (385).

Fatal pulmonary toxicity (acute respiratory distress syndrome) has been reported as a rare side effect of gemcitabine therapy (387). Symptoms include progressive dyspnea, tachypnea, marked hypoxemia, and bilateral interstitial infiltrates consistent with pulmonary edema. Some patients have responded to the termination of gemcitabine therapy and treatment with corticosteroids and diuretics. Prior radiation therapy to the mediastinum may be a risk factor for gemcitabine-induced pulmonary edema (387,388).

Possible incompatibilities between gemcitabine solutions and other drug solutions have not been studied.

Ifosfamide

Chemistry

In combination with cisplatin, ifosfamide (IFEX, Holoxan) is a commonly used drug for the first-line treatment of patients with advanced cancer of the cervix, and in combination chemotherapy, it is a second-line treatment for patients with advanced cancer of the ovary (389,390). It also has activity in advanced or recurrent endometrial cancer (391). Chemically, ifosfamide is 3-(2-chloroethyl)-2-[(2-chloroethyl)amino]-tetrahydro-2H-1,3,2-oxazaphosphorine-2-oxide, and is chemically related to the nitrogen mustards and a structural analog of cyclophosphamide. It differs only in the position of one of the 2 chloroethyl groups, which is transposed to the endocyclic (ring) nitrogen in ifosfamide. The molecular formula is $C_7H_{15}Cl_2N_2O_2P$, and the compound has a molecular weight of 261.1.

Mechanism of Action

Ifosfamide is a metabolically activated alkylating agent. Like cyclophosphamide, it must first undergo hydroxylation by microsomal (mixed-function oxidase) enzyme systems (392). The activation of ifosfamide occurs more slowly than that of cyclophosphamide, and there is quantitatively greater oxidation of the chloroethyl side chains with ifosfamide. This leads to a greater production of chloroacetaldehyde, a possible neurotoxin.

The activation process generates highly reactive metabolites, particularly 4-hydroxyifosfamide, which are capable of cellular uptake and, ultimately, covalent binding to protein and to DNA (393). Metabolites can spontaneously break down to yield the bladder irritant acrolein and the active alkylating moiety, ifosforamide mustard. Cross-linking of DNA strands proceeds from ifosforamide mustard, but acrolein binds nonspecifically and covalently to bladder epithelium. The DNA-cross-link distance is greater for ifosfamide (7 atoms) compared with cyclophosphamide (5 atoms). Furthermore, the aziridine forms more slowly and is less reactive since it lacks a positive charge (394). Chain scission of DNA and inhibition of thymidine uptake also occur with ifosfamide. The primary mechanism of alkylation is not cell cycle specific.

Drug Disposition

The pharmacokinetics of ifosfamide appears to be qualitatively similar to that of cyclophosphamide. Creaven and coworkers (395) found a plasma half-life of radiolabeled ifosfamide ($5,000 \text{ mg/m}^2$) of 13.8 hours, with 82% urinary (radioactivity) recovery.

The plasma decay pattern appears to be biexponential (2-compartment model) for large bolus doses and monoexponential (one-compartment model) with fractionated doses. In contrast to single-dose pharmacokinetics studies, Allen and associates (396) found that with sequential daily administration of $2,400 \text{ mg/m}^2/\text{day}$ for 3 days, there is monoexponential

plasma decay with a half-life of 6.9 hours and a metabolized urinary recovery fraction of 72.8%, in contrast to the biexponential decay (plasma half-life 15.2 hours) of a single-bolus dose of ifosfamide (5,000 mg/m²). This finding suggests that the metabolic disposition of the drug may be dose dependent. These half-lives are approximately twice those reported for cyclophosphamide. Of note, a longer ifosfamide half-life may be seen in obese patients who are more than 20% over ideal body weight. The renal clearance rate of ifosfamide is about twice that for cyclophosphamide: 21.3 versus 10.7 mL/min in bolus dosing and 18.7 versus 10.7 mL/min with fractionated doses. Only about half of an ifosfamide dose is metabolized compared with approximately 90% for cyclophosphamide. This reflects a substantial difference in the metabolic clearance capacity for the 2 analogs. Although more intact (inactive) ifosfamide than cyclophosphamide is renally excreted, urinary alkylating activity persists longer with ifosfamide.

Creaven and coworkers (395) demonstrated that because unchanged ifosfamide, but not metabolites, penetrates the blood-brain barrier, alkylating activity in the CSF may occur but is probably negligible.

Administration and Dosage

Ifosfamide is reconstituted by the addition of sterile water to the vial, which should be shaken to dissolve. Ifosfamide may be further diluted to a concentration of 0.6 to 29.0 mg/mL in 5% dextrose or 0.9% sodium chloride. It is administered intravenously, usually by a short infusion. Ifosfamide may also be administered by slow IV push in a 75-mL minimal volume of sterile saline solution but not water and infused over at least 30 minutes or by continuous infusion over 5 days. Large single doses of ifosfamide produce much more toxicity than fractionated schedules, which are therefore preferred in solid-tumor treatment regimens. Adequate hydration of the patient before and for 72 hours after ifosfamide therapy is recommended to reduce the incidence of drug-induced hemorrhagic cystitis. The use of a concurrent prophylactic agent for hemorrhagic cystitis, such as mesna (Mesnex), is required to prevent severe hematuria from high-dose ifosfamide. At least 2 L of fluid each day is recommended to produce a copious urine output.

Continuous infusions of ifosfamide over 24 hours have also been given every 3 weeks (397). Mesna can be given concurrently in the same infusion container or as a 4-hour intermittent IV bolus (398). However, renal toxicities may be increased with the single, large infusions. Extravasation of the drug should not cause tissue necrosis, but one such case has been described (399).

The FDA-approved dose for testicular cancer is 1,200 mg/m²/day for 5 consecutive days every 21 days. Other dosage schedules include 2,000 mg/m² IV continuous infusion on days 1 to 3 every 21 days as part of the MAID regimen (mesna, Adriamycin, ifosfamide, dacarbazine) for soft-tissue sarcoma; 1,000 mg/m² on days 1 and 2 every 28 days as part of the ICE regimen (ifosfamide, carboplatin, etoposide) for non-Hodgkin's lymphoma; and 1,000 mg/m² on days 1 to 3 every 21 to 28 days as part of the TIC regimen (paclitaxel, ifosfamide, carboplatin) for head and neck cancer (79).

A phase II study evaluated ifosfamide (1,500 mg/m² IV over 1 hour, days 1 to 3) with mesna in combination with paclitaxel (175 mg/m², IV over 3 hours on day 1) and cisplatin (75 mg/m² IV over 2 hours on day 2) as first-line therapy in advanced, suboptimally debulked epithelial ovarian cancer patients (400). This regimen was associated with an 85% objective response rate and a median overall survival of 52.8 months in 22 patients with stage III or IV disease. A regimen of paclitaxel (175 mg/m²), ifosfamide (5,000 mg/m²), and cisplatin (75 mg/m² or 50 mg/m² in irradiated patients) every 21 days in 45 recurrent or persistent cervical cancer patients was associated with a 67% objective response rate (401).

Morgan and colleagues (402) evaluated several IV push and infusion dose schedules in non-small cell lung cancer: 700 to 900 mg/m²/day by IV push for 5 days repeated every 3 weeks; 700 to 1,000 mg/m²/day for 5 days repeated every 3 weeks plus 1 g/day of oral ascorbic acid; 4 g/m² slow infusion repeated every 3 weeks; and 900 mg/m² by IV push weekly. There appeared to be less hematuria produced with the sequential 5-day schedule with concomitant ascorbic acid.

Rodriguez and colleagues (403) described a 47% response rate in leukemia patients with continuous infusions of ifosfamide at 1,200 mg/m²/day given for 5 days. Significant genitourinary toxicity was not encountered, and myelosuppression predominated as the dose-limiting toxicity. In combination with other cytotoxic drugs, such as doxorubicin or lomustine (CCNU), a single IV push dose of 1,000 mg/m² (not to exceed 12,500 g total) has been recommended.

Side Effects and Toxicities

Creaven and associates (395) reviewed the clinical toxicity of ifosfamide given as a large bolus injection (200 to 10,000 mg/m²) and in a fractionated 3-day (2,400 mg/m²/day) schedule. Urinary tract toxicity is the dose-limiting factor with both schedules. The clinical hallmark is hemorrhagic cystitis, which is caused by excretion of active alkylating metabolites into the urinary bladder. Vigorous hydration with oral and IV fluids and concomitant mesna are needed to prevent serious ifosfamide-induced bladder damage. Hydration may also overcome the antidiuretic effects of this drug. Nelson and colleagues (398) used IV furosemide (20 to 40 mg) to maintain adequate urine flow in a phase I study of ifosfamide. Diuretic responses usually occurred within 1 hour.

Symptoms of dysuria and urinary frequency appear to parallel those of hematuria. The onset of symptoms is 1 to 2 days after injection, with an average duration of 9 days (range, 1 to 41 days) (404). Dose-related ifosfamide-induced nephrotoxicity was detected by elevation of BUN, producing subsequent dose-related uremia in 66% of patients receiving 150 mg/kg. Other lesions seen at autopsy (4 of 7 patients) included evidence of acute tubular necrosis and pyelonephritis. At low daily doses, granular cylindruria was seen in all patients, denoting marked tubular damage. The cylindruria cleared within 10 days of drug discontinuance (404). DeFronzo and co-researchers (405) also described glomerular dysfunction and a Fanconi-type picture in a patient treated with ifosfamide. Prior cisplatin therapy may also increase ifosfamide-induced nephrotoxicity (406,407).

Nausea and vomiting appear to be common and are more severe after a rapid injection of large ifosfamide doses. Emesis typically begins within a few hours of administration and persists for an average of 3 days (range, 1 to 28 days) (404).

Hematologic toxicity from ifosfamide usually involves only a mild to moderate degree of leukopenia in most patients. In a review by Creaven and coworkers (395), significant thrombocytopenia was not encountered for any of the dose schedules used.

Lethargy and confusion are seen with high doses of ifosfamide and may be caused by the chloroacetaldehyde metabolite. Nelson and associates (398) observed that this lasted from 1 to 8 hours, was spontaneously reversible, and was related to the passage of intact drug into the central nervous system (CNS). Seizures, ataxia, stupor, and weakness have been reported after ifosfamide. These effects may be increased by concomitant neurotoxic drugs, such as certain antiemetics, tranquilizers, narcotics, and antihistamines. There is a single case report of nonconvulsive status epilepticus associated with ifosfamide therapy. The patient responded to discontinuation of the ifosfamide and phenytoin therapy (408). Although alkylating metabolites appear to penetrate the blood-brain barrier, the levels achieved are too low to be useful in the treatment of CNS tumors (395).

Alopecia is usually seen with ifosfamide, especially when large bolus doses are used. In a study by Van Dyk et al. (404), the average onset of maximal hair loss was 19 days (range, 11 to 32 days) after the start of treatment.

Hepatic enzyme elevations have been described in some patients. The elevations in alkaline phosphatase and serum transaminase are transient and typically resolve rapidly without sequelae.

Special Precautions

The patient must be kept well hydrated during ifosfamide therapy to reduce the potential for hemorrhagic cystitis. The use of mesna given IV or orally is required to prevent hemorrhagic cystitis. Table 14.5 outlines the recommended mesna schedule for ifosfamide uroprotection.

Patients who have received previous or concurrent therapy with radiation or cytotoxic drugs may require significant ifosfamide dosage reductions. Dose reductions should also be considered for patients with impaired renal function and/or serum albumin concentrations below 3.5 g/dL.

Drug Interactions

Several drug interactions are possible with ifosfamide. Because the compound undergoes hepatic activation by microsomal enzymes, induction is potentially possible by pretreatment with various enzyme-inducing drugs, such as phenobarbital, phenytoin, and chloral hydrate.

Nephrotoxic drugs like cisplatin may significantly increase ifosfamide renal damage (406). Other drug interactions reported for cyclophosphamide that may also occur with ifosfamide include reactions with metabolic alteration of H₂-antihistamines, such as cimetidine.

Irinotecan

Chemistry

Irinotecan (CPT-11, Camptosar), a TOPO-I inhibitor, is a water-soluble semisynthetic derivative of camptothecin, a natural product extracted from the stem wood of the *Camptotheca acuminata* tree, that has significant antitumor activity. It was approved by the FDA in 1998 for the treatment of patients with progressive metastatic colon or rectal cancer following 5-FU therapy. Early clinical development of camptothecin was halted because of severe, unpredictable hemorrhagic cystitis, vomiting, and myelosuppression. Subsequently, irinotecan was formulated as a prodrug to have greater water solubility, increased antitumor activity, and less toxicity than the parent compound. Its chemical name is (4S)-4,11-diethyl-4-hydroxy-9-[(4-piperidino)carbonyloxy]-1Hpyrano[3',4':6,7]indolizino[1,2-b]quinoline-3,14(4H,12H) dione hydrochloride trihydrate. This drug

has a molecular weight of 677.19 and the empirical formula is C₃₃H₃₈N₄O₆ · HCl · 3H₂O.

Mechanism of Action

Irinotecan's cytotoxicity is believed to be related to the inhibition of TOPO-I, an enzyme necessary for DNA replication (298). Irinotecan is activated to the active metabolite SN-38 by the liver (409). Irinotecan and SN-38 bind to the transient TOPO-I-DNA complex, stabilize the complex, and thereby promote DNA single-strand breaks. These strand breaks prevent DNA replication and result in cell death (298,409). Current research suggests that the cytotoxicity of irinotecan is due to DNA damage produced during DNA synthesis. Mammalian cells cannot repair these double-strand breaks.

Drug Disposition

Pharmacokinetic studies performed by Rothenberg et al. (410) have determined that when irinotecan is administered as a 90-minute IV infusion at dose ranges of 50 to 180 mg/m², the plasma terminal-phase half-life for irinotecan (total) was 7.9 ± 2.8 hours, 6.3 ± 2.2 hours for irinotecan (lactone), and 11.5 ± 3.8 hours for SN-38 (the active metabolite). The time of peak plasma concentration for irinotecan was at infusion end, whereas the time of peak concentration for total SN-38 varied from 30 to 90 minutes after completion of the infusion. Plasma clearance was unrelated to dose, with a mean clearance of 15.3 ± 3.5 L/h/m² for the total and 45.6 ± 10.8 L/h/m² for the lactone. At the 150-mg/m² dose, the following pharmacokinetic parameters were observed: peak plasma concentration, 1.97 µg/mL for total irinotecan; 0.83 µg/mL for the lactone form; and 36.7 ng/mL for total SN-38; and concentration-time product (AUC) 8.44 µg · h/mL for total irinotecan, 2.81 µg · h/mL for the lactone form, and 409.8 ng · h/mL for total SN-38. Renal excretion was not a major route of drug elimination.

Abigeres et al. (411) determined in their pharmacokinetic study of irinotecan (100 to 700 mg/m² by 30-minute IV infusion) that the plasma disposition of irinotecan was biphasic or triphasic. The mean plasma terminal-phase half-life, volume of distribution, and total body clearance of irinotecan were 14.2 ± 0.9 hours, 157 ± 8 L/m², and 15 ± 1 L/m²/h, respectively. Both the irinotecan and SN-38 concentration-time product (AUC) increased linearly with dose. At the 350-mg/m² dose level, the irinotecan and SN-38 AUCs were 34.0 ± 4.1 µg · h/mL and 451 ± 100 ng · h/mL, respectively. The plasma terminal-phase half-life of SN-38 was 13.8 ± 1.4 hours.

Administration and Dosage

The appropriate dose of irinotecan should be diluted with 500 mL of dextrose (5%) to a final concentration of 0.12 to 1.1 mg/mL and administered IV over 90 minutes (410). Alternatively, French investigators have administered irinotecan by diluting the appropriate amount of drug in 250 mL of 0.9% sodium chloride solution and delivering the drug IV over 30 minutes (411).

In the United States, the recommended dose for irinotecan therapy in colon cancer patients is 125 mg/m² weekly by 90-minute infusion for 4 weeks followed by a 2-week rest. In Europe, the recommended dose is 300 to 350 mg/m² by 90-minute infusion every 21 days. The U.S. schedule has been used in 3 phase II clinical trials, wherein irinotecan displayed modest activity in cervical cancer patients (412–414). When administered as a single dose every 3 weeks, a 240 mg/m² dose is recommended (410,415). French investigators have determined that a 600 mg/m² 30-minute IV infusion every 3 weeks can be administered if drug-induced diarrhea is aggressively managed by high-dose loperamide (e.g., up to 16 mg/day); however, these investigators recommended a dose level of 350 mg/m² every 3 weeks until further experience is gained with higher dose levels (411).

Table 14.5 Dosing Schedules for Mesna Combined with Ifosfamide

Route of Mesna Administration	Dose (mg/kg) as a Percentage of Ifosfamide Dose at Times before and after Ifosfamide		
	15 min before	4 hr after	8 hr after
Intravenous	20%	20%	20%
Oral ^a	Not recommended; use IV route	0%	0%

^aFor highly reliable patients with total emetic control, mesna solution can be diluted 1:1 to 1:10 in carbonated cola drinks or in chilled fruit juices (e.g., apple, grape, tomato, and orange juice) and administered orally.

Side Effects and Toxicities

Diarrhea and neutropenia are the major dose-limiting toxicities associated with irinotecan (410,411,415). Other moderate to severe toxicities associated with irinotecan therapy include anemia, dehydration (secondary to diarrhea), nausea, vomiting, anorexia, abdominal cramping, cumulative asthenia, thrombocytopenia, renal insufficiency, elevations in liver transaminases, and alopecia.

The diarrhea associated with irinotecan appears to be due to 2 separate mechanisms. The diarrhea that may occur during irinotecan infusion is highly responsive to atropine therapy and, therefore, appears to be related to cholinergic activity. However, the subacute diarrhea that develops 2 to 3 weeks after irinotecan therapy is refractory to anticholinergic agents. The most effective treatment for the subacute diarrhea is institution of therapy with antimotility agents (i.e., loperamide or diphenoxylate hydrochloride with atropine sulfate) at the first signs of increased intestinal motility (e.g., loose bowels). If left untreated, subacute diarrhea can rapidly progress to grade 4 toxicity. This life-threatening diarrhea is refractory to antidiarrheal therapy and generally lasts for 5 to 7 days. Patients with grade 4 diarrhea should be hospitalized and receive supportive care with IV fluids and electrolyte replacement (410).

Special Precautions

As described above (see Side Effects and Toxicities section), irinotecan can induce grade 4 diarrhea that is refractory to antidiarrheal medication. Patients receiving irinotecan must be monitored carefully for early symptoms of increased intestinal motility and should receive antimotility therapy (e.g., up to 16 mg/day loperamide) as soon as initial symptoms of diarrhea appear. A low level of glucuronidation in the biliary system has been associated with the development of severe diarrhea in some patients (416). It has been shown that uridine diphosphate glucuronosyltransferase isoform 1A1 (UGT1A1) is responsible for conjugating SN-38 to form the glucuronide and that patients with low UGT1A1 activity are prone to increased toxicity from irinotecan (417). Patients with certain genetic polymorphisms in UGT1A1 have a reduced capacity for glucuronidation and are more likely to suffer serious toxicity (418).

Special Applications

The TOPO-I inhibitor irinotecan also has shown activity against advanced cervical cancer. Cottu and colleagues (419) reported response rates in patients with relapsed cervical cancer ranging from 20% to 22%. The GOG reported a response rate of 13.3% (6 of 45) in patients with advanced cervical cancer with no prior chemotherapy (413). No responses were reported in second-line (after resistance to cisplatin) treatment in a phase II study of 16 patients (412). However, Verschraegen et al. (414) reported a 21% response rate in the same patient population ($n = 42$). Reviews by Eisenhauer and Vermorken (420) and Verschraegen et al. (421) reported response rates ranging from 13% to 24%. The combination of irinotecan (60 mg/m² 90 min IV on days 1, 8, and 15) followed by cisplatin (60 mg/m² on day 8) administered every 3 weeks, demonstrated activity in a phase II trial of first-line treatment of cervical cancer, with 1-year disease-free and overall survival rates of 26.7% and 65.1%, respectively (422).

Liposomal Encapsulated Doxorubicin

Chemistry

Liposomal doxorubicin (Doxil, Caelyx) is FDA approved for the treatment of patients with metastatic, refractory ovarian cancer and AIDS-related Kaposi's sarcoma. Doxorubicin HCl, which is the established name for (8S,10S)-10-[(3-amino-2,3,6-trideoxy-

α -L-xylo-hexopyranosyl)oxy]-8-glycolyl-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1-methoxy-5,12-naphthacenedione hydrochloride, has a molecular weight of 579.99, and the molecular formula is $C_{27}H_{29}NO_{11} \cdot HCl$. The liposomal carriers are composed of N-(carbonyl-methoxypolyethylene glycol 2000)-1,2 distearoyl-*sn*-glycero-3-phosphoethanolamine sodium salt (MPEG-DSPE), 3.19 mg/mL; fully hydrogenated soy phosphatidylcholine (HSPC), 9.58 mg/mL; and cholesterol, 3.19 mg/mL. Greater than 90% of the drug is encapsulated in the liposomes. The liposomal encapsulation of doxorubicin dramatically alters the pharmacokinetic and toxicity profiles of the drug.

Mechanism of Action

The mechanism of action of doxorubicin is discussed previously (see Doxorubicin section). Liposomes are microscopic vesicles composed of a phospholipid bilayer that are capable of encapsulating active drugs. The liposomes of the encapsulated form of doxorubicin are formulated with surface-bound methoxypolyethylene glycol (MPEG), a process often referred to as pegylation, to protect liposomes from detection by the mononuclear phagocyte system (MPS) and to increase blood circulation time (423).

Drug Disposition

Liposomal doxorubicin is associated with a much longer plasma half-life, slower plasma clearance, and reduced volume of distribution than free doxorubicin. In a pharmacokinetics study performed in 6 patients with solid tumors, the area under the plasma disappearance curve was 1.0 mg/L hour versus 609 mg/L hour when 25 mg/m² of doxorubicin was administered as free drug or as a pegylated liposomal form, respectively. The initial half-life was 0.07 versus 3.2 hours, and the terminal half-life was 8.7 versus 45.2 hours for the free and liposomal forms of doxorubicin, respectively. Additionally, the steady-state volume of distribution was 254 L versus 4.1 L for the free and liposomal forms, respectively (424). Liposomal encapsulation of doxorubicin has also been shown to result in fourfold to 16-fold increases in tumor-tissue drug concentrations compared with the free form.

Administration and Dosage

Liposomal doxorubicin must be diluted in 250 mL of 5% dextrose prior to administration. Because liposomal doxorubicin contains no preservative or bacteriostatic agent, aseptic technique must be strictly observed. Liposomal doxorubicin may be administered as an IV infusion over 30 to 60 minutes. In that liposomal doxorubicin is not a vesicant, extravasation of the drug is not a critical concern. For ovarian cancer patients, liposomal doxorubicin should be administered at a dose of 50 mg/m² (every 4 weeks) at an initial rate of 1 mg/min to reduce the risk of infusion reactions. The rate may be increased to a 60-minute infusion if no adverse events are noted. The recommended dose in AIDS-related Kaposi's sarcoma patients is 20 mg/m² over 30 minutes, once every 3 weeks, for as long as the patient responds and tolerates treatment.

Side Effects and Toxicities

Unlike the parent drug, liposomal doxorubicin is not a vesicant and is associated with minimal cardiotoxicity, alopecia, and nausea/vomiting. However, the liposomal encapsulation results in acute infusion reactions and an increased rate of PPE and stomatitis (425). PPE is a dose-limiting toxicity that can occur in 26% of patients who receive 50 mg/m² every 4 weeks (426). Stomatitis is a second dose-limiting toxicity associated with liposomal doxorubicin. Current methods to prevent PPE and stomatitis include dose reduction and discontinuation (grade 1—redose; if patient has experienced previous grade 3 or 4 toxicity, delay the treatment by 2 weeks until resolution to grades 0 to 1 and

reduce dose by 25% before returning to the original dose level; grades 2 to 4—delay up to 2 weeks until resolved, if no resolution to grades 0 to 1, discontinue; grades 3 to 4—after delay and resolution to grades 0 to 1, decrease dose by 25%, if no resolution, discontinue). To help relieve pain from PPE, topical wound care, elevation, and cold compresses may be used as supportive care (351). Topical DMSO has been used to treat skin extravasations (99% DMSO 4 times daily up to 14 days), but has yet to be evaluated in a randomized trial (349). Other possible therapies that are yet to be evaluated in clinical trials include systemic corticosteroids and pyridoxine (vitamin B₆) (351).

Infusion-related reactions occur in less than 10% of patients treated with liposomal doxorubicin and are most common during the first course of treatment. Symptoms may include flushing, shortness of breath, facial swelling, headache, chills, back pain, tightness in the chest and throat, and hypotension. Alopecia has been observed in only 15% of ovarian cancer patients treated with liposomal doxorubicin.

Melphalan

Chemistry

Melphalan (Alkeran, L-phenylalanine mustard, L-PAM) is a phenylalanine derivative of nitrogen mustard that acts as a bifunctional alkylating agent. Melphalan is FDA approved for the chemotherapy of patients with multiple myeloma. The agent's molecular formula is C₁₃H₁₈Cl₂N₂O₂ and its molecular weight is 305.2. It is known chemically as 4-[bis(2-chloroethyl) amino]-L-phenylalanine. Melphalan is water insoluble and previously was only commercially available in a 2-mg tablet form. However, a parenteral formulation was approved by the FDA in 1993. Melphalan for injection is supplied as a freeze-dried powder in single-use vials containing 50 mg melphalan and 20 mg povidone. A vial of sterile diluent (10 mL) is also supplied.

Mechanism of Action

Melphalan is an alkylating agent of the bischloroethylamine type. Its cytotoxicity appears to be related to the extent of its interstrand cross-linking with tumor-cell DNA, probably by binding at the N⁷ position of guanine (427). The cross-helical base pairing causes strain and possible rupture of the double-stranded DNA backbone.

Melphalan is relatively stable in media containing high concentrations of chloride ions and at acidic pH (427). It has a relatively short *in vitro* half-life in plasma of approximately 2 hours, owing to the rapid hydroxylation of the chloroethyl groups of the molecule. Melphalan may form a reactive immonium ion that can alkylate or hydroxylate the monohydroxy and dihydroxy metabolites. Monohydroxy melphalan possesses only 2% of the cytotoxicity of the parent compound, and the dihydroxy derivative is inactive (428).

Melphalan is usually transported into cells by 2 amino acid-transporting systems: the sodium-independent system that transfers leucine and a monovalent cation-dependent system similar to that which transfers alanine, serine, or cysteine (429). Melphalan efflux from cells appears to be sodium independent, to be stimulated by amino acids in the extracellular medium, and to occur by a simple diffusion mechanism.

Drug Disposition

Melphalan has extremely variable systemic availability after oral administration. In the average patient, approximately one-third of an administered dose of melphalan can be recovered from plasma after a bolus oral dose. The range of systemic availability after oral dosing varies from 0% to greater than 90%. The terminal-phase plasma half-life of orally administered melphalan is approximately 90 minutes, and the 24-hour urinary excretion

rate averages 11% (430). Melphalan penetration into cerebrospinal fluid is low. Plasma protein binding ranges from 60% to 90%, and approximately 30% is irreversibly bound to plasma proteins.

Studies of melphalan metabolism, using an isolated perfused rat liver model and *in vitro* rat microsomal enzyme preparations, have documented insignificant hepatic biotransformation (431).

Two groups of investigators have reported that the systemic availability of melphalan is increased if the drug is administered in the fasting state. The presence of a large meal appears to enhance melphalan degradation at the alkaline pH found in the upper small bowel before systemic absorption (432,433).

Patients with multiple myeloma receiving IV melphalan achieved longer durations of survival than those receiving the oral formulation. Furthermore, a significantly lower dose of IV drug was associated with life-threatening leukopenia and infectious complications compared with the oral formulation (433).

Administration and Dosage

The usual IV dose is 16 mg/m² (15- to 20-minute infusion), administered at 2-week intervals for 4 doses, then at 4-week intervals. The oral agent dose is 6 mg/day for 2 to 3 weeks, followed by up to 4 weeks without treatment. As a single agent, one-time IV doses of 1 mg/kg repeated at 4- to 6-week intervals are generally well tolerated. Although the manufacturer reports equal effects from IV or oral doses, bioavailability differences and the potential for lessened hepatic clearance of IV doses suggest IV dosing at reduced levels. In a surgical adjuvant setting for ovarian carcinoma, melphalan has been used in large cyclic doses of 1 mg/kg given IV over 8 hours and repeated in 4 weeks (434). The apparently equivalent therapeutic results with IV and oral dosing are surprising in light of the reported poor oral absorption of the compound.

Side Effects and Toxicities

Compared with other standard alkylating agents, melphalan is relatively well tolerated after oral administration. Except for dose-limiting bone marrow suppression (i.e., neutropenia, thrombocytopenia, anemia), other acute side effects are uncommon and include nausea and vomiting and, rarely, skin rash and pulmonary toxicity (435). Melphalan is characterized by its potential to cause cumulative bone marrow damage, as expressed by profound and prolonged depression of neutrophils and platelets. There is a slow reduction in peripheral leukocyte and platelet counts to their nadirs at 28 to 35 days after drug administration followed by a 14- to 21-day recovery period.

Acute nonlymphocytic leukemia has been reported in patients with multiple myeloma and ovarian cancer after prolonged melphalan therapy. In one Swedish study of 474 patients with ovarian carcinoma, there were 4 cases of acute nonlymphocytic leukemia among 12 patients who received 800 mg or more of melphalan (436). An evaluation of the relationship between alkylating agents and leukemic disorders in 3,363 one-year survivors of ovarian cancer revealed that the 10-year cumulative risk of acquiring leukemia was 11.2% after treatment with melphalan and 5.4% after cyclophosphamide treatment (437). The risk of developing leukemia after melphalan and cyclophosphamide treatment was significantly higher than in matched patient groups who received no chemotherapy. These data suggest that to reduce the leukemia risk, the total dose of melphalan should not exceed 600 mg.

Special Applications

One major impediment to the success of cancer chemotherapy is the rapid development of drug resistance as manifested clinically by short objective responses and subsequent, progressive

tumor growth despite aggressive chemotherapy. Several mechanisms have been postulated to explain this relatively universal phenomenon.

Melphalan therapy has been used in autologous bone marrow transplantation. A series of studies have been reported for high-dose (120 to 225 mg/m²) IV-administered melphalan against adult melanoma, breast, and colon cancers (438,439). Although the resulting high response rates appear to be promising, most have been partial, and survival advantages have not yet been established. In general, these high doses of melphalan have been tolerated relatively well, with diarrhea and stomatitis becoming severe and dose-limiting at doses greater than 200 mg/m².

Because ovarian cancer remains confined to the IP space for most of its natural history, there has been increasing interest in the IP administration of cytotoxic drugs to patients with minimal residual IP disease (i.e., plaques <1 cm in diameter) after aggressive cytoreductive surgery or primary chemotherapy. Melphalan exhibits a high degree of *in vitro* cytotoxicity compared with other standard chemotherapeutic agents when tested against fresh human ovarian cancer tumors at drug concentrations achievable by IP administration (440). In addition to its high degree of cytotoxicity, melphalan's high molecular weight ensures a relatively low clearance from the peritoneal space.

In a phase I dose-finding study, Howell and coworkers (441) showed that an IP melphalan dose of 70 mg/kg was tolerated, with only moderate leukopenia (median nadir 2,000 cells/ μ L) and thrombocytopenia (median nadir 69,000 platelets/ μ L) and no evidence of peritoneal irritation. The peak peritoneal concentration averaged 93-fold greater than the plasma concentration, and total drug exposure for the peritoneal cavity averaged 63-fold greater than that for the plasma.

Methotrexate

Chemistry

Methotrexate is an active drug in the first-line treatment of gestational choriocarcinoma, chorioadenoma destruens, and hydatidiform mole. It is used in the prophylaxis and treatment of meningeal leukemia, and is used in combination with other agents for the treatment of breast cancer, epidermoid cancers of the head and neck, advanced mycosis fungoides, advanced non-Hodgkin's lymphoma, lung cancer, and metastatic squamous-cell cancer of the cervix. Methotrexate is a cell cycle-specific antifolate analog, which differs from folic acid in 2 substitutions: an amino group for a hydroxyl in the pteridine portion of the molecule and a methyl group on the amino nitrogen between the pteridine nucleus and the benzoyl group of 4-amino-10-methyl folic acid. Chemically, methotrexate is N-[4-[(2,4-diamino-6-pteridinyl)methyl]benzoyl]-L-glutamic acid. It is a weak acid, with a molecular weight of 454.45 and a molecular formula of C₂₀H₂₂N₈O₅. It is only slightly soluble in water and alcohol. Sodium methotrexate is water soluble and is used in injectable preparations.

Mechanism of Action

Free intracellular methotrexate tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolic acid, the active form of folic acid. As a result, thymidylate synthetase and various steps in *de novo* purine synthesis that require 1-carbon transfer reactions are halted. This in turn arrests DNA, RNA, and protein synthesis.

Amino acid syntheses blocked by methotrexate include those requiring 1-carbon transfer, such as the conversion of glycine to serine and homocysteine to methionine. Experimental studies have shown that thymidylate synthetase is inhibited at methotrexate concentrations of 10⁻⁸ M or less, but inhibition of purine synthesis requires concentrations of 10⁻⁷ M or greater (442).

Methotrexate undergoes a variable degree of polyglutamation intracellularly. The polyglutamated forms of the drug are positively charged and do not readily pass through cell membranes. Methotrexate polyglutamates form an intracellular pool of active drug that is retained for long periods, sometimes months, after a single dose (443). The ability of tumor cells to add t-glutamyl residues to methotrexate may be a key determinant of antitumor activity.

The effects of methotrexate are rapidly reversible as free methotrexate leaves the cells. The normal intracellular levels of dihydrofolate are very low (10⁻⁸ M) but increase greatly after methotrexate administration.

Resistance to methotrexate may develop as a result of elevated dihydrofolate reductase activity or defective transport of methotrexate into malignant cells. Increased dihydrofolate reductase enzyme levels may also result from amplification of the dihydrofolate reductase gene, a process associated with homogeneously staining regions of chromosomes and an unstable inheritance mediated by double minutes or extra chromosomal DNA fragments (444). Certain quinazolines have been shown to be effective inhibitors of thymidylate synthetase and may be useful clinically in overcoming this type of resistance (445). *In vitro* studies and clinical experimentation with high-dose therapy indicate that a major mechanism of resistance is probably secondary to decreased cellular uptake.

Methotrexate is classified as a cell cycle phase-specific antimetabolite with activity mostly in S phase. Experimentally, methotrexate synchronizes tumor cells in S phase about 36 to 72 hours after administration (446).

The enhanced toxic effect on tumors compared with normal tissue from high-dose methotrexate with leucovorin rescue may be a result of bypassing normal carrier-mediated cell membrane transport of methotrexate. Leucovorin and its metabolite, 5-methyltetrahydrofolate, share a common influx transport site with methotrexate. There appear to be at least 2 active transport carrier systems involved in the influx and efflux of methotrexate and folates (447). If normal cells are rescued with calcium leucovorin, methotrexate can then exert a relatively greater toxic effect on the tumor cells. Selective rescue of normal cells may be mediated by a slower rate of DNA synthesis relative to the tumor cell or to tissue-specific differences in transmembrane transport.

Drug Disposition

Orally administered methotrexate is rapidly but incompletely absorbed from the gastrointestinal tract. It reaches peak blood levels in approximately 1 hour. Approximately 50% to 60% of the drug in the blood is bound to plasma proteins. Methotrexate is widely distributed to body tissues. In conventional doses, methotrexate is excreted unchanged in the urine. In high doses, it is partially metabolized to 7-hydromethotrexate, which is only slightly soluble in acidic solutions. Approximately 1% to 11% of a dose is excreted as the 7-hydroxy metabolite, and this may comprise as much as 35% of the drug level in the terminal elimination phase. Only about one-third of an oral dose is absorbed, but intramuscular absorption is almost 100% (448).

The hepatic extraction coefficient for methotrexate appears to be very low, and intraarterial hepatic doses show metabolism and pharmacokinetics similar to those of IV doses (449). Methotrexate is both filtered at the glomerulus and actively secreted by the renal tubule. Drugs that interfere with renal excretion of weak acids, such as probenecid, sulfinpyrazone, and salicylates, may reduce the rate of methotrexate excretion. Probenecid has been used successfully in one study to produce a prolonged elevation of plasma methotrexate levels from otherwise low doses of methotrexate (450).

Plasma decay of methotrexate levels have been reported to be biphasic and possibly triphasic. Huffman and associates (451)

reported half-lives after a 30 mg/m² dose to be triphasic: 0.750 ± 0.11, 3.49 ± 0.55, and 26.99 ± 4.44 hours, respectively. Stoller and colleagues (452) reported a biphasic plasma decay for high-dose therapy of 2.06 ± 0.16 and 10.4 ± 1.8 hours. Wang and coresearchers (453) reported age-dependent biphasic elimination of high-dose methotrexate.

Patients with pleural effusions may accumulate methotrexate that slowly distributes from this compartment back into the plasma to increase systemic exposure and the risk of toxicity (454). Effusions should be drained before administration of methotrexate.

Administration and Dosage

Methotrexate may be given by the oral, intramuscular, IV (IV infusion or push), intraarterial, or intrathecal routes. For treatment of neoplastic disease, oral administration of low-dose methotrexate is preferred, owing to the rapid absorption of the tablet form of the agent. Methotrexate has been given by numerous dosing schedules. The usual starting doses are adjusted based on clinical response and hematologic monitoring. In general, methotrexate is administered orally or intramuscularly in doses of 15 to 30 mg daily for a 5-day course. Courses are usually repeated 3 to 5 times as required, with rest periods of 1 or more weeks between courses until toxicities subside (455). Leucovorin is indicated following treatment with higher doses of methotrexate to diminish toxicity.

If the IV formulation is administered, the dose should be reduced by 50% for patients with renal insufficiency (BUN ≥30 mg/L). Similar dose reductions should be made for the oral form, although no specific guidelines are available. Methotrexate administration is contraindicated in patients with a creatinine clearance less than 40 mL/min and/or a serum creatinine greater than 2 mg/dL.

Side Effects and Toxicities

Hematologic effects of methotrexate include leukopenia, thrombocytopenia, and anemia. They occur rapidly and depend on the dose and schedule used. The nadir of hemoglobin depression occurs after 6 to 13 days, and of reticulocyte at 2 to 7 days, with rebound between 9 and 19 days. Leukocyte nadir occurs within 4 to 7 days, followed by partial recovery and then, in rare instances, a second decrease in the leukocyte counts occurs during days 12 to 21. The platelet nadir is reached in 5 to 12 days. Hypogammaglobulinemia may also occur after methotrexate administration.

Nausea, vomiting, and anorexia are usually the earliest gastrointestinal symptoms. Gingivitis, glossitis, pharyngitis, stomatitis, and ulcerations with bleeding of the mucosal membranes of the mouth or other portions of the gastrointestinal tract may occur. If ulcerative stomatitis or diarrhea occurs, methotrexate therapy must be interrupted to prevent severe hemorrhagic enteritis or intestinal perforation.

Hepatotoxicity is more common in patients receiving high-dose therapy and in those receiving frequent small doses. Hepatocellular injury is indicated in liver function tests by a rise in serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT), usually within the first 12 hours. Prothrombin times may rise with a decrease in plasma factor VII activity, and indirect hyperbilirubinemia may develop. All of these usually return to normal within 1 week. Hepatocytes appear to be protected by fractionated high-dose methotrexate treatments with leucovorin rescue if treatments are administered at intervals of less than 1 week. This may be due to leucovorin activity remaining from prior doses. Various pathologic hepatic changes can occur, including atrophy, necrosis, fatty changes, fibrosis, and cirrhosis. Liver biopsy is the only reliable means of assessing the degree of methotrexate hepatotoxicity.

Dermatologic side effects include erythematous rashes, pruritus, urticaria, folliculitis, vasculitis, photosensitivity, depigmentation, or hyperpigmentation. Alopecia may occur, with several months being required for regrowth. CNS effects include dizziness, malaise, and blurred vision. Encephalopathy also has been reported. Intrathecal administration has been followed by increased CSF pressure, convulsions, paresis, and a syndrome resembling the Guillain-Barré syndrome (384). Deaths have been reported after intrathecal therapy. Renal failure may occur in patients receiving methotrexate, especially in high doses. This risk may be decreased by alkalization of the urine to increase methotrexate solubility and by giving large quantities of fluid. Other reactions rarely reported include chills and fever, osteoporosis, and pulmonary reactions, mainly fibrosis (456).

Drug Interactions

Potential drug interactions have been postulated to occur with other protein-bound drugs, such as salicylates, sulfonamides, phenytoin, and *p*-aminobenzoic acid. These drugs displace methotrexate from its protein-binding site in the blood, causing an increase in the levels of the free drug. However, the overall degree of binding is probably not high enough for major displacement interactions.

Antibiotics used in gut sterilization may also alter methotrexate pharmacokinetics in humans, eliminating the slow phase of excretion (457). Salicylates and probenecid may also compete with methotrexate for renal tubular secretion and increase its serum half-life.

Ethyl alcohol may increase the possibility of methotrexate-induced hepatotoxicity. Oral anticoagulants, such as warfarin, may be greatly potentiated by methotrexate. Methotrexate may alter the liver metabolism of these drugs.

There are several drug interactions described for methotrexate with other chemotherapeutic agents. For example, a clinically significant interaction between methotrexate and L-asparaginase involves the administration of methotrexate 3 to 24 hours before L-asparaginase. The methotrexate treatment is believed to block protein synthesis and reduce asparaginase toxicities, allowing larger doses to be given. Some sequential methotrexate combinations may produce enhanced therapeutic activity. For example, methotrexate given 4 to 9 hours before 5-FU may produce enhanced antitumor activity in breast cancer, but with a commensurate increase in toxic effects (201,458). The mechanism of this interaction involves a significant increase in 5-FU for at least 3 hours (458). The reverse sequence decreases therapeutic activity (459).

Methotrexate activity is enhanced, and thus toxicity increased, when it is used with aspirin, penicillins, nonsteroidal anti-inflammatory agents, cephalosporins, or phenytoin. These agents inhibit the renal excretion of methotrexate (79).

Special Applications

Very high doses of methotrexate have been administered for a variety of tumors. Although leucovorin rescue reduces toxicity, it is still not clear whether high-dose therapy is superior to more conventional dosing without rescue. Specific dosing schemes vary, but a high dose of methotrexate is usually administered IV and followed by calcium leucovorin 24 to 36 hours after initiation of therapy to prevent toxicity. Table 14.6 presents specific dosing recommendations.

The dose range of methotrexate with leucovorin rescue is 100 mg/m² to 10 g/m² given every 1 to 3 weeks. The lower end of this dosing spectrum has been administered in 4 divided oral doses over a 24-hour period. Most frequently, the dose is given by IV infusion in 1 to 2 L of fluid as a rapid infusion or over 6 to 24 hours. Higher peak methotrexate levels occur with more rapid IV infusions, and this may be theoretically more efficacious. There does not appear to be a clinical difference in

Table 14.6 Determination of Leucovorin Dose for High-Dose Methotrexate (50–250 mg/kg over 6 hours) Regimens

Plasma Methotrexate Concentration at 48 hr (M)	Leucovorin Plasma Administration	
	mg/m ² of Leucovorin Every 8 hr	No. of Doses of Leucovorin
$<5 \times 10^{-7}$	15	7
5×10^{-7}	15	8
1×10^{-6}	100	8
2×10^{-6}	100	8

Note: Plasma methotrexate concentration at 96 hours should be determined also. If the plasma concentration at 96 hours is $\geq 5 \times 10^{-6}$ M, the previously used leucovorin regimen should be continued until the plasma methotrexate concentration is $\leq 5 \times 10^{-7}$ M. All patients should also be prehydrated for 12 hours to establish an alkaline diuresis using 1.5 L/m² of fluid containing 10 mEq of bicarbonate and 20 mEq of KCl (pH of urine should be 7.0).

toxicity between rapid and prolonged infusions. Only the 500- and 1,000-mg vials with no preservative should be used for this purpose. Further dilution of methotrexate is necessary and can be accomplished with normal saline or D₅W.

High-dose methotrexate has been associated with reversible nephrotoxicity. At high concentrations, methotrexate may precipitate in the renal tubule, causing tubular dilatation and damage. The pK_a of methotrexate is 5.4. When the urine pH is near this value, methotrexate exists predominantly in its insoluble form and is likely to precipitate. Renal toxicity may be prevented by increasing urine alkalinity and flow. Sodium bicarbonate (3 g every 3 hours for 12 hours before therapy) is usually sufficient to induce alkaline urine in adults. The sodium bicarbonate should be continued with frequent urine pH checks during the therapy and for 48 hours after the dose has been delivered. Methotrexate serum levels are useful in predicting toxic reactions and appropriately adjusting rescue doses of leucovorin (460,461). High-dose methotrexate with rescue is complicated and potentially extremely toxic. Only experienced teams using carefully designed protocols should attempt this treatment. Immediate methotrexate levels should be readily available. Fatal renal or hematologic reactions have occurred at major treatment centers despite the prophylactic precautions described (462).

Mitomycin

Chemistry

Mitomycin (Mutamycin, mitomycin C) is a purple antibiotic isolated from *Streptomyces caespitosus* that is indicated for disseminated adenocarcinoma of the stomach or pancreas in combination with other agents and as palliative treatment. It has also been proven to be useful in combination chemotherapy as a third-line agent in the treatment of advanced cervical cancer. Its chemical name is [1aR]-6-amino-8-[[[(aminocarbonyl)oxy]methyl]-1,1a,2,8,8a,8b-hexahydro-8a-methoxy-5-methylazirino[2',3':3,4]-pyrrolo[1,2-a]indole-4,7-dione, and it has a molecular weight of 334. Mitomycin is heat stable, is soluble in water and other organic solvents, and has a unique absorption peak at 365 nm (463). In solution, it is slowly inactivated by visible but not ultraviolet light. It is very unstable in acidic and highly basic conditions. The aziridine and carbamate groups on mitomycin are necessary for alkylating activity but not for antibacterial activity. The compound is activated by reduction of the quinone moiety, which releases a methanol residue from the molecule. This allows the aziridine ring to open, exposing an electrophilic carbon at C₁ (alkylating site). The second

(cross-linking) site for alkylation is exposed at C₁₀ after an enzymatic or chemically mediated loss of the carbamate side chain.

Mechanism of Action

Mitomycin is activated *in vivo* to an alkylating agent that cross-links complementary DNA strands, halting DNA synthesis. DNA is the major site of mitomycin activity, although at extremely high concentrations, RNA synthesis may also be affected. The active metabolites of mitomycin resulting from reduction of the quinone moiety yield an opened aziridine ring exposing the primary alkylating site at C₁. A second alkylating site at C₁₀ is exposed with the enzymatic loss of the carbamate side chain (464). The molecular site of DNA binding has been identified at the N₂ and O₆ positions of adjacent guanines in the minor groove of DNA (465).

Activation of the drug can be mediated by chemical reducing agents, by microsomal enzymes, or even by brief exposure to an acidic pH. The extent of DNA binding appears to be related to the guanine and cytosine content of the particular DNA. Cytotoxicity probably results directly from DNA synthesis inhibition secondary to alkylation.

Oxygen free radicals may also contribute to the cytotoxicity of mitomycin by producing DNA strand breaks (466). Oxygen free radicals are produced by cyclic redox reactions of the quinone moiety. Mitomycin's cytotoxic action is not cell cycle phase-specific, but cytotoxic effects are maximized if cells are treated in late G₁ and early S phase. In addition to the direct cytotoxic effects of the drug, mitomycin also causes chromosomal aberrations (mutagenic activity), and in experimental systems, it is a potent carcinogen and teratogen.

Kennedy and coworkers (467) described selective activation of mitomycin by hypoxic cells, suggesting some drug selectivity for hypoxic tumors. Resistance to mitomycin involves an increase in specific cytosolic proteins (possibly a glutathione transferase) and collateral resistance with anthracyclines and dactinomycin (468,469). The latter type of multidrug resistance is mediated by P-glycoprotein expression, with resultant enhanced drug efflux, as observed in mitomycin C-resistant L-1210 cells (470).

Drug Disposition

Mitomycin is cleared rapidly from the vascular compartment. Peak serum concentrations of about 1 µg/mL are typically achieved after IV bolus doses of 10 mg/m² (471). Less than 10% of the dose is excreted into the urine, and this is complete within a few hours after administration. Mitomycin also has been detected in the bile and feces, although animal studies demonstrate that the highest drug levels occur in the kidneys. Detectable levels were also found in muscle, lung, intestine, stomach, and eye, but not in the brain, spleen, or liver (463).

The primary means of mitomycin elimination is by liver metabolism, but the specific enzymes responsible are unknown. However, the enzymes responsible for metabolism do not appear to involve the P450 mixed-function oxide family. *In vitro* studies demonstrate drug inactivation on contact with tissue preparations from the spleen, liver, kidney, brain, and heart. This inactivation is further augmented by anaerobic conditions (463).

There is no detectable change in mitomycin pharmacokinetics in patients with altered hepatic function or when other drugs, including furosemide, are given concurrently (471,472). Schilcher and colleagues (473) showed that the pharmacokinetics of mitomycin does not change after the administration of high doses.

Mitomycin distribution into bile and ascites fluids has been quantitated in patients receiving standard IV doses. The maximum biliary level of 0.5 µg/mL was achieved after 2 hours and was five- to eightfold higher than simultaneous plasma levels during the elimination phase (474). Mitomycin also rapidly

penetrates into ascites fluid and reaches maximal concentrations of 0.05 $\mu\text{g/mL}$ 1 hour after administration. This distribution represents approximately 40% of the total plasma exposure. The drug also appears to slightly concentrate in cervical tissues after IV administration (475).

With intraarterial administration, the hepatic extraction of mitomycin averages only 23% (476). The calculated relative advantage for hepatic arterial infusions is only 2.5- to 3.6-fold greater than for other methods.

Administration and Dosage

Sterile water (10 mL) should be added to each 5-mg vial of mitomycin and shaken gently to dissolve. Mitomycin should be administered IV to avoid extravasation of the drug. If extravasation occurs, severe local tissue necrosis may occur (477). The drug is usually given by a slow IV push, with continuous patient monitoring to lessen the chance of extravasation. Short infusions in 100 to 150 mL of D₅W or normal saline have also been used. Vein patency should be checked before the administration of any dose using 5 to 10 mL of fluid that does not contain the drug. The same procedure should follow the dose. This flushes any remaining drug from the tubing and the venipuncture site.

The recommended dose of mitomycin used as a single agent is 20 mg/m^2 given IV every 6 to 8 weeks. In combination with other myelosuppressive drugs, mitomycin doses are typically limited to 10 mg/m^2 every 6 to 8 weeks. Bolus doses greater than 20 mg/m^2 produce severe toxicity without greatly enhancing efficacy.

Repeat dosing of mitomycin should be based on adequate marrow recovery, including leukocytes, platelets, and erythrocytes. Leukocyte count should return to 4,000/ mm^3 and platelet count to 100,000/ mm^3 .

An ambulatory continuous infusion of mitomycin has been administered at 0.75 $\text{mg/m}^2/\text{day}$ for consecutive 50-day dosing (478). A dosing regimen of 3 $\text{mg/m}^2/\text{day}$ for 5 days every 4 to 6 weeks has also been used (478). These regimens are believed to deliver greater dose intensity by reducing myelosuppression. Intraarterial perfusion doses of 20 mg/m^2 have been given every 6 to 8 weeks (479).

Side Effects and Toxicities

Bone marrow suppression involving platelets, leukocytes, and erythrocytes is the most serious toxicity, and it can continue for 3 to 8 weeks after drug administration is halted (463). Myelosuppression, particularly anemia, can be cumulative. This has been minimized by keeping total lifetime doses under 50 to 60 mg/m^2 .

Gastrointestinal disturbances in the form of nausea, vomiting, and anorexia occasionally develop. These reactions are usually not severe and have an onset within 1 to 2 hours after administration. They may persist for several hours. Stomatitis may also occur, but it is generally not severe.

Renal toxicity detected by increasing serum BUN and creatinine levels with glomerular dysfunction is occasionally seen. This does not appear to be dose- or treatment-duration related, and it is usually not severe. However, mitomycin can also induce a microangiopathic hemolytic anemia with progressive renal failure (hemolytic-uremic syndrome) and cardiopulmonary decompensation. This disease is fatal within 3 to 4 weeks of diagnosis, although the onset is typically delayed for months after mitomycin administration (480). The incidence of this toxic effect may approach 10% among patients given large cumulative doses (480). In one series, renal complications from mitomycin developed in 1.6% of 63 patients receiving a total dose of 50 mg/m^2 or less, 11% of 37 patients receiving 50 to 69 mg/m^2 , and 28% of 18 patients receiving total doses greater than 70 mg/m^2 (481). This suggests that a threshold for inducing microangiopathic hemolytic anemia may be a cumulative dose of about 50 mg/m^2 of mitomycin. Signs of the disease

include thrombocytopenia, circulating schistocytes, and acute renal failure. Histopathologic examinations of the kidneys reveal fibrin thrombi in arterioles, tubular atrophy, and widespread glomerular necrosis.

Veno-occlusive disease of the liver has been reported after high-dose mitomycin therapy and autologous bone marrow transplantation (482). Signs include progressive hepatic dysfunction, abdominal pain, and ascites. Although this rarely has been observed with low-dose therapy, it appears to be much more frequent after high-dose regimens.

Alopecia may occur after mitomycin therapy, but it is usually not severe. Rarely, purple bands in the nail beds correspond to sequential doses of the drug. Lethargy or weakness may occur and can last from several days to 3 weeks. Fatigue and some drowsiness or confusion has also been observed. Dose-related skin reactions and fever with drug administration are occasionally seen.

Severe soft-tissue ulcers may also be expected if the drug escapes the vein during administration. Mitomycin extravasation injuries can result in chronic ulcers that can expand over months (477). Particularly distressing aspects of some mitomycin extravasations include the delayed (3 to 4 months) and sometimes distal occurrence of soft-tissue ulceration after uneventful injections in a peripheral vein (483,484). In animals, the only effective antidote to mitomycin skin reactions was topical DMSO (99% DMSO). Mitomycin extravasations may be empirically treated with topical application of 1.5 mL of DMSO every 6 hours for 14 days (485).

Interstitial pneumonia thought to be secondary to mitomycin has been reported in a small number of patients. These patients showed rapid improvement after treatment with corticosteroids (486).

Special Precautions

Myelosuppression may be cumulative with successive doses of mitomycin and may necessitate dose reductions. Careful monitoring of blood counts is critical. Serious local ulceration may occur if the drug is delivered outside the vein. Extravasation of mitomycin must be avoided.

Clinically significant antitumor drug synergy in humans has yet to be described for mitomycin, although it is probably at least additive in several drug combinations, including the FAM regimen (5-FU, doxorubicin, mitomycin) used in gastrointestinal cancer, the MOB regimen [mitomycin, vincristine (Oncovin), bleomycin] used in carcinoma of the uterine cervix, and megestrol acetate in patients with advanced breast cancer.

Special Applications

Mitomycin and IP hyperthermia were combined to prophylactically treat patients with gastric cancer (487). Mitomycin (8 to 100 $\mu\text{g/mL}$) was administered continuously in bags containing 2,000 mL of heated (40°C to 45°C) saline solution. The total perfusion was 8 to 12 L over 50 to 60 minutes, comprising a mitomycin C dose of 64 to 100 mg. Low peak plasma levels (0.1 $\mu\text{g/mL}$) were produced, and approximately 39% of the administered dose was retained intraperitoneally. The half-lives of mitomycin C in the perfusate are 10 to 17 minutes (α) and 70 to 120 minutes (β) (488). Serum protein levels decreased significantly during and after the procedure, indicating that serum protein reaccumulates in the peritoneal space.

Mitomycin (5 to 10 mg) has also been given every 28 days combined with cisplatin (100 mg/m^2) using the IP route. Mitomycin was always given 1 week after cisplatin, and the dose was diluted in 2 L of normal saline. In 11 patients with malignant peritoneal mesothelioma, 5 of 8 previously untreated patients had reduced fluid reaccumulation lasting from 2 to 32 months (median, 5 months) (292). The major toxic reaction was pain, and catheter failure was related to the IP mitomycin.

Oxaliplatin

Chemistry

Oxaliplatin (Eloxatin, diaminocyclohexane platinum, DACH platinum) is a third-generation platinum with the molecular formula $C_8H_{14}N_2O_4Pt$ and the chemical name of *cis*-[(1*R*,2*R*)-1,2-cyclohexanediamine-*N,N'*][oxalato(2-)-*O,O'*]platinum, and it has a molecular weight of 397.3. Oxaliplatin is an organo-platinum complex in which the platinum atom is complexed with 1,2-diaminocyclohexane (DACH) and with an oxalate ligand as a leaving group. Oxaliplatin is slightly soluble in water (6 mg/mL), slightly soluble in methanol, and practically insoluble in ethanol and acetone. It is FDA approved for second-line treatment in metastatic colorectal cancer in combination with fluoropyrimidines.

Mechanism of Action

Oxaliplatin binds to DNA in a manner similar to cisplatin, in that it binds to repeating deoxyguanosines d(GpG) in a single DNA strand. It reacts with DNA to produce intrastrand cross-links (>90%) at adenine-guanine d(ApC) sites and to produce intrastrand cross-links (<5%) with guanosines of opposing DNA strands (dG)₂ (79,189). This results in inhibition of DNA synthesis, function, and transcription. Oxaliplatin reacts more rapidly with DNA to form these interlinks and intralinks (e.g., within 15 minutes) than the other platinum agents (12 hours for cisplatin and over 24 hours for carboplatin) (189). Furthermore, unlike the other platinum-DNA adducts, mismatch repair enzymes are unable to recognize the adducts formed by oxaliplatin because of their bulkier size (79).

Drug Disposition

In a summary of pharmacokinetic studies, plasma platinum C_{max} values have been shown to be in the range of 2.59 to 3.22 $\mu\text{g/mL}$, and mean AUC_{0-48h} in the range of 50.4 to 71.5 $\mu\text{g/mL} \cdot \text{hour}$ after an oxaliplatin dose of 130 mg/m^2 (2-hour infusion) (489). Inpatient and outpatient variability was moderate to low (23% and 6%, respectively) (490). In 1-hour infusion studies, mean plasma platinum C_{max} and AUC_{0-24h} increased in a dose-dependent fashion up to 180 mg/m^2 . The pharmacokinetics of platinum in ultrafiltrate after administration of oxaliplatin are triphasic and characterized by short α (0.28 hour) and β (16.3 hours) distribution phases, which are followed by a long terminal γ phase (273 hours) (489). Oxaliplatin is primarily cleared from plasma by renal excretion (53.8%) and covalent tissue binding. Clearance is not affected by age, gender, or hepatic impairment (489).

Administration and Dosage

Oxaliplatin is reconstituted by adding 10 mL sterile water for each 50-mg vial, or dextrose (5%). The solution must be further diluted in 250 to 500 mL of 5% dextrose prior to administration. The infusion line should be flushed with D₅W prior to administration of any concomitant medication (490). Premedication with antiemetics is recommended.

The recommended dose for metastatic colorectal cancer is as follows: on day 1 of every 2-week cycle, oxaliplatin (85 mg/m^2) is generally administered intravenously with leucovorin (200 mg/m^2) over 120 minutes at the same time in 2 separate bags using a Y-line, followed by 5-FU (400 mg/m^2 IV bolus), followed by 5-FU (600 mg/m^2) in 500 mL D₅W as a 22-hour continuous infusion. On day 2, the patient should receive leucovorin (200 mg/m^2) over 120 minutes at the same time in 2 separate bags using a Y-line, followed by 5-FU (400 mg/m^2 IV bolus), followed by 5-FU (600 mg/m^2) in 500 mL D₅W as a 22-hour continuous infusion.

In phase II trials for gynecologic cancers, the recommended dose of oxaliplatin is 130 mg/m^2 IV over 2 hours every 21 days (491,492).

Side Effects and Toxicities

Oxaliplatin produces dose-limiting peripheral neuropathy and gastrointestinal and hematologic adverse events. Neurotoxic symptoms usually resolve within a week of stopping therapy; however, symptom intensity is cumulative with repeated courses of oxaliplatin (189,490,493). Other common adverse events include mild leukopenia and mild to moderate thrombocytopenia. Nausea and vomiting are common, and antiemetic prophylaxis is required with oxaliplatin therapy.

Unlike other platinum-containing agents, oxaliplatin is not associated with nephrotoxicity. Alopecia has not been reported with oxaliplatin.

Special Applications

Oxaliplatin is an agent with substantial activity in platinum-sensitive ovarian cancer patients previously treated with cisplatin. Bougnoix and colleagues (494) noted 2 complete and 8 partial responses in 24 patients who were platinum sensitive (41.7% response rate). Similar findings were seen in a phase II study, which also saw a 42% response rate in platinum-sensitive patients (495). Chollet and colleagues (496) studied similar populations of patients and noted 6 responses in 13 platinum-sensitive patients (46%) and a 17% response rate (3 of 18 patients) in platinum-resistant patients. Phase II studies have seen only minimal activity in platinum-resistant patients (<6% response rate) (491,495).

Paclitaxel

Chemistry

Paclitaxel (Taxol) is one of the most commonly used drugs in oncology, with FDA approval for primary or salvage therapy for epithelial ovarian cancer, as salvage therapy for metastatic breast cancer, in second-line treatment of AIDS-related Kaposi's sarcoma, and in the treatment of non-small cell lung cancer. It is also active against a variety of other solid tumors, including cervical and endometrial cancer (427,428). It is a diterpene plant product derived from the bark of the Pacific yew, *Taxus baccata*. It has a molecular weight of 853.9, is insoluble in water, and has an empiric formula of $C_{47}H_{51}NO_{14}$. Its chemical name is 5 β ,20-epoxy-1,2 α ,4,7 β ,10 β ,13 α -hexahydroxytax-11-en-9-one-4,10-diacetate 2-benzoate 13-ester with (2*R*,3*S*)-*N*-benzoyl-3-phenylisoserine.

Mechanism of Action

Paclitaxel acts as a mitotic spindle poison. In a manner contrary to known mitotic spindle inhibitors, such as colchicine and podophyllotoxin, paclitaxel promotes assembly of microtubules and stabilizes them, preventing depolymerization. This inability to depolymerize microtubules prevents cellular replication (177).

Drug Disposition

Early pharmacokinetic studies using standard doses and a 24-hour infusion suggested that paclitaxel pharmacokinetics were linear; however, with short infusions and/or high dose levels, paclitaxel's nonlinear pharmacokinetics becomes readily apparent (239). The nonlinearity is due to saturable distribution, metabolism, and elimination. Terminal elimination half-life is largely dependent on the dose and administration schedule. At a dose level of 175 mg/m^2 with a 3-hour infusion, mean pharmacokinetic parameters of paclitaxel include the following: plasma $t_{1/2\alpha}$, 16 minutes; plasma $t_{1/2\beta}$, 140 minutes; plasma $t_{1/2\gamma}$, 18.75 hours; plasma clearance, 12.69 L/h/m²; plasma AUC, 16.81 $\mu\text{mol/L} \cdot \text{hour}$; 48-hour urinary excretion, <10% of dose; and 48-hour fecal excretion, 70% of dose (239).

Clearance is rapid and not due to urinary excretion; the major route of paclitaxel elimination is believed to be via hepatic

metabolism and subsequent biliary excretion (497). Approximately 70% to 80% of the drug is eliminated by fecal excretion.

Administration and Dosage

All patients undergoing paclitaxel therapy should receive premedication to prevent severe hypersensitivity reactions. A recommended regimen is dexamethasone (either 20 mg orally the night before treatment and the morning of treatment, or 20 mg IV 30 minutes before paclitaxel delivery) plus diphenhydramine (50 mg) and famotidine (20 mg) IV 30 minutes before chemotherapy (498). For the majority of patients, administration of dexamethasone 20 mg IV 30 to 60 minutes before paclitaxel is sufficient and has been proven to be effective in preventing hypersensitivity reactions.

Paclitaxel is commercially available as an injection concentrate in 30-mg (5 mL), 100-mg (16.7 mL), and 300-mg (50 mL) multidose vials. Before infusion, paclitaxel must be diluted with 0.9% sodium chloride, 5% dextrose, 5% dextrose and 0.9% sodium chloride injection, or 5% dextrose in Ringer's injection to a final concentration of 0.3 to 1.2 mg/mL. The solution is stable for up to 27 hours at room temperature. Paclitaxel should be administered through an in-line filter with a microporous membrane not greater than 0.22 μm to remove particulates that are present in paclitaxel solutions. Although particulate formation does not indicate loss of drug potency, solutions exhibiting excess particulate matter formation should be discarded. Because of the possibility of leaching of phthalate plasticizers with paclitaxel solutions, only nonpolyvinylchloride (such as polyethylene or polyolefin) IV administration sets should be used.

As a result of an unacceptable level of severe hypersensitivity reactions in early phase I studies (most likely related to the Cremaphor EL vehicle), a 24-hour infusion schedule and a premedication regimen with corticosteroids and histamine H_1 - and H_2 -antagonists were used in all phase II and III clinical trials conducted in the United States from 1987 to 1992. Later clinical studies established that a 3-hour paclitaxel infusion schedule can be administered safely without a significant increase in major hypersensitivity reactions and that the shortened infusion schedule is associated with significantly less grade 4 neutropenia than the 24-hour infusion (i.e., 71% vs. 18% for the 24- and 3-hour infusions, respectively) (499). Follow-up studies have determined that a 1-hour infusion schedule also is feasible; however, infusion durations less than 1 hour are associated with a prohibitively high rate of hypersensitivity reactions (500).

There were early concerns that the shorter infusion schedules might be associated with a decline in efficacy. However, results from GOG-158, a phase III, randomized study in women with optimal disease, advanced ovarian cancer, revealed that paclitaxel 175 mg/m^2 by 3-hour infusion combined with carboplatin (targeted AUC of 7.5) (arm II) had similar activity with less toxicity than paclitaxel 135 mg/m^2 by 24-hour infusion plus cisplatin 75 mg/m^2 (arm I) (501). Median progression-free survival and overall survival were 19.4 and 48.7 months, respectively, for arm I (paclitaxel-cisplatin) compared with 20.7 and 57.4 months, respectively, for arm II (paclitaxel-carboplatin). Because of its ease of administration and lower toxicity profile (cisplatin plus short-infusion paclitaxel is associated with dose-limiting neurotoxicity), the recommended primary chemotherapy regimen for advanced ovarian cancer is paclitaxel 175 mg/m^2 by 3-hour infusion plus carboplatin (targeted AUC of 6.0 to 7.5) every 21 days for 6 cycles (501). Although this generally is a well-tolerated regimen, neurosensory toxicity and prolonged thrombocytopenia can prove to be dose limiting. The FDA-approved regimen for first-line treatment of ovarian cancer is paclitaxel 135 mg/m^2 over 24 hours plus cisplatin 75 mg/m^2 every 21 days for 6 cycles or paclitaxel 175 mg/m^2 over 3 hours plus cisplatin 75 mg/m^2 .

The FDA-approved recommended regimen for salvage therapy for patients with platinum-refractory ovarian cancer is paclitaxel 135 or 175 mg/m^2 administered IV over 3 hours every 3 weeks, but the optimal regimen has not clearly been established. Paclitaxel has been administered by various other schedules during investigational studies in patients with solid tumors, including 135 to 250 mg/m^2 as a 24-hour continuous infusion every 3 weeks; 212 to 225 mg/m^2 as a 6-hour infusion every 3 weeks; 30 mg/m^2 as a 1-hour infusion daily for 5 days every 3 weeks; 30 mg/m^2 as a 6-hour infusion daily for 5 days every 3 weeks; 120 to 140 mg/m^2 as a 96-hour infusion every 3 weeks; and 150 mg/m^2 as a 120-hour infusion every 3 weeks (177). Most recently, IP therapy for optimally debulked advanced ovarian cancer demonstrated a significant survival advantage with a regimen of IV paclitaxel on day 1, IP cisplatin on day 2, and IP paclitaxel on day 8 (see Intraperitoneal Drug Pharmacokinetics and Cisplatin sections of this chapter for more details on this IP regimen) (4,154,155,502).

Weekly schedules of paclitaxel have been explored extensively, particularly in combination with carboplatin, although there are few data comparing them with 3-weekly regimens. They are generally reported as being well-tolerated in relapsed disease, with some responses reported in patients previously exposed to the 3-weekly schedule (503,504). A randomized study comparing weekly versus 3-weekly paclitaxel has been conducted in breast cancer. Five hundred and seventy-seven patients were randomized and an additional 158 patients were included in the sample. The combined sample showed a statistically significant improvement in response rate, time to progression and overall survival (505), with neurotoxicity as the dose-limiting toxicity.

Special Precautions

Before the institution of standard prophylactic medications, the incidence of major hypersensitivity reactions associated with paclitaxel therapy approached 25% to 30%. With premedication, the incidence of severe hypersensitivity reactions has decreased to less than 2%. The majority of paclitaxel-induced hypersensitivity reactions can be categorized as grade 1, with symptoms of dyspnea with bronchospasm, urticaria, and hypotension. Major sensitivity reactions usually occur within the first 10 minutes after the first or second dose of paclitaxel (177). Minor symptoms of flushing and rashes are not predictive of the future development of severe manifestations (177,499). According to National Cancer Institute guidelines for paclitaxel administration, emergency equipment must be available and medical personnel should be in attendance during paclitaxel infusion, especially during the first 15 minutes of the first and second courses. Vital signs should be periodically monitored during the first several hours of drug infusion. The paclitaxel infusion should be discontinued immediately if symptoms of a major hypersensitivity reaction occur (including respiratory distress, hypotension, generalized urticaria, and angioedema). Severe hypersensitivity reactions may be treated with IV epinephrine, IV diphenhydramine, IV fluids, and nebulized β -agonists. Steroid therapy may be helpful in the resolution of recurrent symptoms (506). There is strong evidence that patients who develop major hypersensitivity reactions may be successfully retreated with slow, low-dose infusions of paclitaxel after premedication with multiple high doses of corticosteroids and antihistamines (507).

Drug Interactions

Paclitaxel therapy appears to modify the hematologic toxicity associated with platinum agents. Rowinsky et al. (508) conducted a phase I study of sequential escalating doses of paclitaxel and cisplatin therapy and determined that myelosuppression was more severe when paclitaxel was administered immediately after cisplatin therapy than when given prior to cisplatin.

Concomitant medications that contain substrates or inhibitors of hepatic enzymes, principally cytochrome P450 isoenzymes CYP_{2C8} and CYP_{3A4}, may increase paclitaxel clearance, and caution should be exercised when administering paclitaxel. In a study by Chang et al. (509), the pharmacokinetics of paclitaxel was significantly altered by the concomitant use of anticonvulsants (i.e., phenytoin, carbamazepine, and phenobarbital), and the maximum tolerated doses of paclitaxel in malignant glioma patients were 360 mg/m² for those on anticonvulsant therapy versus 240 mg/m² for those not receiving anticonvulsants. There was also a significant difference in paclitaxel metabolite and toxicity profiles between the 2 groups. Central neurotoxicity, rather than neutropenia, was the dose-limiting toxicity in patients on anticonvulsant therapy who received paclitaxel at a dose greater than 350 mg/m².

Special Applications

Paclitaxel is a particularly promising agent for IP administration in that this route of drug delivery results in a more than 3-log increased exposure of the peritoneal cavity relative to systemic circulation. Additionally, potentially cytotoxic levels of paclitaxel remain in the peritoneal cavity for 5 to 7 days following IP administration; therefore, weekly IP treatment results in continuous drug exposure (510). A phase II study in women with ovarian, fallopian, or peritoneal cancer and small-volume residual disease following primary chemotherapy showed that IP paclitaxel had significant activity as evidenced by a 61% surgically defined complete response rate (511). Three large phase III trials in the GOG and the Southwest Oncology Group (GOG-104/SWOG-8501, GOG-114, and GOG-172) comparing various combination chemotherapeutic regimens administered IV or IP documented significant survival advantages for the IP treatment arms (3–5). Most recently, in GOG-172, an IP regimen (IV paclitaxel, 135 mg/m² over 24 hours on day 1, IP cisplatin 100 mg/m² on day 2, and IP paclitaxel 60 mg/m² on day 8, every 21 days) was associated with a 25% reduction in the risk of death compared to the IV administered regimen (IV paclitaxel plus cisplatin) ($p = 0.03$) (4). The day 1 paclitaxel may alternatively be given over 3 hours to reduce the myelosuppressive activity of paclitaxel and to eliminate the need for a hospital stay (154).

Paclitaxel has demonstrated activity against both endometrial and cervical cancers (512). Woo and colleagues (513) reported a 43% response rate to paclitaxel (95% CI: 6% to 80%) in 7 patients with advanced, progressive, or recurrent endometrial cancer following platinum analog treatment. A GOG study noted a 14.3% complete and 21.4% partial response rate in 28 evaluable patients with endometrial cancer not previously treated with chemotherapy (514). Leukopenia was the most prominent side effect noted. A response rate of 37% (95% CI: 16% to 62%) was reported in 19 patients pretreated with cisplatin, doxorubicin, and cyclophosphamide (515). A GOG phase II trial of paclitaxel (3-hour infusion of 200 mg/m² every 21 days or 175 mg/m² for patients with prior pelvic radiation therapy) found a 27.3% response rate (95% CI: 15% to 42.8%) in 44 persistent or recurrent endometrial cancer patients who failed prior chemotherapy (516).

A GOG phase II trial of single-agent paclitaxel in advanced cervical cancer demonstrated a response rate of 31% (427). Trials of combination cisplatin-paclitaxel (IV paclitaxel 175 mg/m² by 3-hour infusion followed by cisplatin 75 mg/m²) in metastatic and recurrent cervical cancer showed moderate activity (47% response rate; 95% CI: 30% to 65%) (517). A similar response rate (45%) was seen in another phase II trial of first-line therapy of advanced cervical cancer (IV paclitaxel 135 mg/m² by 24-hour infusion followed by cisplatin 75 mg/m² every 28 days) (518).

Pemetrexed

Chemistry

Pemetrexed (Alimta) is an antifolate antineoplastic agent with the chemical name of L-Glutamic acid, *N*-[4-[2-(2-amino-4,7-dihydro-4-oxo-1*H*-pyrrolo[2,3-*d*]pyrimidin-5-yl)ethyl]benzoyl]-, disodium salt, heptahydrate. It has a molecular weight of 597.49, and its molecular formula is C₂₀H₁₉N₅Na₂O₆ · 7H₂O. Pemetrexed is FDA approved for combination therapy with cisplatin for malignant pleural mesothelioma, and for single-agent therapy for non-small cell lung cancer.

Mechanism of Action

Pemetrexed inhibits the folate-dependent enzymes thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyltransferase (GARFT). The inhibition of GARFT, for example, is directly associated with a decrease in the rate of tumor cells (519). Although methotrexate was an early but potent inhibitor of DHFR, the antifolate activity of pemetrexed is quite different. The K_m for pemetrexed is one hundredth that of methotrexate for folylpolyglutamate synthetase (FPGS), making it possible to rapidly and completely block TS activity; whereas methotrexate acts in a more gradual and cumulative process, only impacting cellular proliferation at the point where more than 95% of the enzyme is inhibited (519). Additional details regarding the unique mechanism of action of pemetrexed, including features of membrane transport, its maintained activity in loss of transport activity, and its comparison with other antifolates (e.g., 5-FU, methotrexate, raltitrexed) are discussed in more detail elsewhere (519).

Drug Disposition

Pemetrexed is primarily excreted in the urine and is only minimally metabolized. The elimination half-life is approximately 3.5 hours among patients with normal renal function. Pemetrexed exposure increases with decreasing renal function. Pemetrexed is 81% bound to plasma proteins, and binding is not affected by renal function.

Administration and Dosage

Pemetrexed is administered IV at 500 mg/m² over 10 minutes on day 1 of every 21-day cycle. When used in combination therapy, cisplatin (75 mg/m² over 2 hours) should begin 30 minutes after the pemetrexed administration. The premedication regimen with pemetrexed includes corticosteroids (dexamethasone) to reduce skin rash reactions and folate-containing vitamin supplementation (daily for at least 7 days prior to pemetrexed administration) to reduce some toxicities.

Side Effects and Toxicities

The most commonly occurring side effects associated with pemetrexed treatment include hematologic toxicity, fever and infection, stomatitis, pharyngitis, and rash. Although many toxicities appeared significantly lower among patients receiving folate supplementation (e.g., neutropenia, nausea, vomiting, fever, infection), hypertension (11% vs. 3%), chest pain (8% vs. 6%), and thrombosis/embolism (6% vs. 3%) were higher among those receiving supplementation. Rare cases of colitis have been reported in postmarketing studies.

Topotecan

Chemistry

Topotecan (Hycamtin, topotecan hydrochloride) was approved by the FDA in 1996 for the treatment of ovarian cancer patients after failure of primary chemotherapy. It is also indicated in the

treatment of small-cell lung cancer after failure of first-line chemotherapy. Topotecan is a semisynthetic analog of camptothecin. The parent compound is derived from the bark of an ornamental tree native to Asia, *Camptotheca acuminata*. Sodium camptothecin was studied in clinical trials in the late 1960s through the early 1970s. However, clinical development of this agent was halted despite evidence of a variety of tumor responses because of severe and unpredictable toxicities (e.g., myelosuppression and hemorrhagic cystitis) (520). Topotecan and other camptothecin analogs (e.g., irinotecan) have been formulated in an effort to overcome unacceptable toxicities and to increase cytotoxicity and water solubility. Topotecan incorporates a stable basic side chain at the 9-position of the A-ring of 10-hydroxycamptothecin, which increases aqueous solubility. The molecular weight is 457.9 (the HCl salt) and the formula is $C_{23}H_{23}N_3O_5 \cdot HCl$ (the free base has a molecular weight of 421.5). The chemical name of topotecan is (S)-10-[(dimethylamino)methyl]-4-ethyl-4,9-dihydroxy-1H-pyrano[3',4':6,7] indolizino [1,2-b]quinoline-3,14-(4H,12H)-dione monohydrochloride.

Mechanism of Action

In a manner similar to camptothecin, topotecan's cytotoxicity results from the inhibition of TOPO-I, an enzyme that induces reversible single-strand breaks during DNA replication. Camptothecin analogs bind with and stabilize the transient TOPO-I-DNA complex, preventing religation of the single-strand breakage. The interaction of the ternary topotecan-TOPO-I-DNA complex with replication enzymes results in double-strand DNA breaks and cellular death. Topotecan exists in a pH-dependent equilibrium as both a closed lactone ring and a hydroxy acid; the hydroxy acid is formed by hydrolysis of the lactone ring. The active lactone form predominates at a pH below 7.0, and at a pH of 6.0, greater than 80% of topotecan exists in the lactone form. Slow reaction kinetics studies have shown that the hydroxy acid is inactive, and only the closed lactone bonds with the TOPO-I-DNA complex (409).

Drug Disposition

After IV administration, plasma pharmacokinetics shows that the lactone form, which is active as an inhibitor of TOPO-I, is rapidly converted to the hydroxy acid form. At the end of a brief infusion, approximately half of the dose administered exits as hydroxy acid (415). One hour after administration, less than 30% of the dose remains in the lactone form. Topotecan does not inhibit TOPO-II.

Both forms of topotecan are subject to rapid biphasic elimination. In a summary of pharmacokinetics studies, the mean half-life of topotecan lactone was only 3.0 hours (range, 1.2 to 4.9 hours) (409). Binding to plasma proteins is approximately 35%. Renal excretion appears to account for 40% to 70% of drug clearance (79,189).

When topotecan was administered as a weekly 24-hour IV infusion of 1 to 2 mg/m², the plasma steady-state concentration and the AUC increased linearly with dose. The lactone to total drug concentration ratio was constant, which suggests that the total drug concentration may be used as a measure of active lactone exposure with weekly, long infusions (521). Additionally, comparison of day 1 pharmacokinetics values with blood counts showed that both the topotecan AUC and lactone AUC were predictive of the level of neutrophil reduction on days 15, 22, and 29 using the sigmoid E_{max} model (521). This led the investigators to suggest that topotecan-induced myelosuppression is noncumulative and that elimination probably remains unchanged with repeat dosing in individual patients. Other studies have also found a correlation between the topotecan AUC and level of neutropenia (415,522).

Limited sampling models for topotecan pharmacokinetics have been proposed that may facilitate tailoring of topotecan drug doses in individual patients and large pharmacodynamic studies of topotecan (523,524). Plasma concentrations of the

lactone and hydroxy acid forms of topotecan at 2 hours, after a 30-minute infusion, reliably predicted the lactone form AUC, the hydroxy acid AUC, the total topotecan AUC, and the clearance rate.

Administration and Dosage

Each 4-mg vial of topotecan should be reconstituted with 4 mL of sterile water. The resulting solution can be further diluted with either 0.9% sodium chloride or 5% dextrose. Because the active lactone form of topotecan is subject to a pH-dependent hydrolysis to the inactive hydroxy acid, consideration should be given to maintenance of an acidic pH during drug infusion. When the topotecan lactone is dissolved in 5% dextrose, only approximately 10% is converted to the hydroxy acid (415). Because the product does not contain an antibacterial preservative, it should be used immediately once constituted.

Parenteral topotecan has been administered by IV infusions varying in length from 30 minutes to 21 days (409). As discussed below, the dosing schedule has a profound effect on the maximum tolerated dose (MTD).

An oral formulation has been evaluated in murine tumor models and in phase I to II trials. It has been associated with excellent bioavailability and similar efficacy compared with parenteral topotecan in 4 of the 5 murine tumor models tested (525). In early phase human trials, oral topotecan was well tolerated and active in second-line therapy of ovarian cancer and small-cell lung cancer, and was associated with less neutropenia than the IV formulation (526–528).

The standard FDA-approved dosing regimen is 1.5 mg/m²/day × 5 days by 30-minute IV infusion every 21 days, for a minimum of 4 courses owing to delayed tumor response, as tolerated (in the absence of tumor progression). However, this dosing schedule is associated with a greater than 80% incidence of grade IV neutropenia. Many oncologists, therefore, use a dose of 1.25 mg/m²/day for 5 days and/or administer prophylactic G-CSF.

In phase I studies, the MTD of topotecan was highly dependent on the length of infusion schedules; longer infusions were generally associated with lower MTDs. The estimated MTD of topotecan when administered as a 30-minute, 72-hour, and 120-hour continuous infusion is 22.5 mg/m², 1.6 mg/m²/day (4.8 mg/m² total), and 0.68 mg/m²/day (3.4 mg/m² total), respectively. As a continuous 21-day infusion administered every 28 days, the MTD of topotecan appears to be 0.5 mg/m²/day (10.5 mg/m²/cycle) (409,529,530). A weekly dosing schedule has been developed that appears to maintain antitumor activity without causing severe myelosuppression (531,532).

Side Effects and Toxicities

Toxicity data are available from a phase III, randomized study of topotecan 1.5 mg/m²/day for 5 days every 21 days versus paclitaxel 175 mg/m² IV over 3 hours every 21 days in ovarian cancer patients with progressive or recurrent disease following primary platinum-based chemotherapy (533). Neutropenia was the predominant toxicity in this study: 79% of patients experienced grade 4 neutropenia, 25% of patients experienced febrile neutropenia, and 5% of patients developed sepsis [2 patients (2%) died of sepsis]. The onset of grade 4 neutropenia, which responded to G-CSF therapy, occurred on days 9 through 15 of a chemotherapy cycle. Thrombocytopenia also occurred frequently: 50% of patients experienced grades 3 to 4 thrombocytopenia (25% experienced grade 4). Grade 4 anemia occurred in 3.6% of patients.

The most common nonhematologic toxicities were cumulative, dose-related alopecia (76%) and nausea/vomiting (10% grades 3 to 4), which was amenable to antiemetic therapy. Other frequent toxicities were fatigue (41%), constipation (43%), diarrhea (40%), abdominal pain (27%), fever in the absence of neutropenia (29%), stomatitis (24%), dyspnea (24%), and asthenia (22%) (533).

Although the results of the study described in the above paragraphs led to the FDA approval of topotecan as salvage therapy for patients with ovarian cancer, with a recommended dose level of 1.5 mg/m²/day for 5 days, it is important to note that the patients in this European study only received one prior platinum-based chemotherapeutic regimen, and that most received cisplatin (not carboplatin), and none had received prior paclitaxel. In general, topotecan-induced myelosuppression is more severe in patients who have previously received carboplatin and/or multiple prior chemotherapeutic regimens. For this reason, many clinicians use an initial topotecan dose of 1.25 mg/m²/day and/or administer prophylactic G-CSF.

Special Precautions

Because topotecan has a high rate of renal excretion and a modest hepatic clearance, a clinical study was conducted to evaluate the impact of renal and hepatic dysfunction on toxicity in patients undergoing treatment with topotecan on a daily $\times$ 5 dosing schedule (534,535). Pharmacokinetic analyses showed clear correlations between creatinine clearance and plasma clearance of both topotecan and topotecan lactone ($r^2 = 0.65$, $p < 0.0001$). Although the standard dose for patients with good renal function is 1.5 mg/m²/day $\times$ 5 days, this study determined that the recommended starting dose for patients with moderate hepatic dysfunction (creatinine clearance of 20 to 39 mL/min) was 0.75 mg/m². The investigators urged extreme caution with topotecan administration in patients with more profound renal insufficiency and recommend further dose reductions for heavily pretreated patients (534). Hepatic insufficiency did not appear to exacerbate hematologic toxicity (534). Nonhematologic toxicity appeared to be unaffected by either renal or hepatic insufficiency.

Drug Interactions

Drug sequence of the paclitaxel/topotecan combination had no apparent impact on hematologic toxicities or pharmacologic behavior (536). However, drug sequence of the cisplatin/topotecan combination did have a significant impact on toxicity and topotecan pharmacokinetics. Prior administration of cisplatin significantly reduced the clearance of topotecan (possibly as a result of subclinical nephrotoxicity) and increased hematologic toxicity (508). In GOG-182, carboplatin was administered on day 3 of a daily $\times$ 3 topotecan administration schedule, because administration of carboplatin on day 1 was associated with excessive neutropenia and thrombocytopenia (537).

There has been interest in sequential administration of topotecan (TOPO-I inhibitor) with TOPO-II inhibitors (e.g., doxorubicin, etoposide). The rationale is that administration of a TOPO-I inhibitor would induce upregulation of TOPO-II in tumor cells and thus enhance cytotoxicity. One clinical/translational study of topotecan (0.17 to 1.05 mg/m²/day as a 72-hour continuous infusion on days 1 to 3) followed by etoposide (75 or 100 mg/m²/day as a 2-hour infusion daily on days 8 to 10) failed to show reliable downregulation of TOPO-I and upregulation of TOPO-II following administration of topotecan (538). Although significant clinical activity was observed in this phase I study in patients with various solid tumors, the investigators concluded that the toxicity and translational research results did not support a significant synergistic advantage of this combination. Another study of the TOPO-I and TOPO-II inhibitor combination therapy (IV topotecan 0.5 mg/m² per day for 5 days and oral etoposide 50 mg twice daily for 7 days of every 21-day cycle, with dose escalation of topotecan 0.75 and 1.0 mg/m²) found the combination to be safe and effective in small-cell lung cancer patients; however, the incidence of grades 3 to 4 neutropenia was 25%, and 2 patients died from neutropenic sepsis (539).

TOPO-I is a biochemical mediator of radiosensitization in cultured mammalian cells by camptothecin derivatives (540). There are *in vitro* and *in vivo* data suggesting that topotecan

may have activity as a radiation-sensitizing agent (541). However, this apparent synergistic relationship remains to be explored in clinical trials.

Special Applications

Phase I trials of IP topotecan have demonstrated the feasibility of IP administration and a favorable toxicity profile (542,543). Pharmacokinetic studies revealed that the pharmacologic advantage associated with IP administration of topotecan (expressed as the ratio of the peritoneal to plasma AUC) was 31.2 (543). In a Netherlands study, patients were treated with escalating doses (5 to 30 mg/m² every 21 days). The dose-limiting toxicity was acute hypotension, chills, and fever at the 30-mg/m² dose level (542). The University of California, San Diego study treated patients with escalating doses from 2 to 4 mg/m² every 21 days. The MTD of IP topotecan was determined to be 4 mg/m² every 21 days, and the recommended dose for further phase II study was 3 mg/m². The dose-limiting toxicity was neutropenia. Other toxicities included anemia, vomiting, fever, and abdominal pain (543).

Vinblastine Sulfate

Chemistry

Vinblastine (Velban) is used in the treatment of germ-cell tumors of the ovary (544) and has demonstrated activity in early clinical trials of cervical, endometrial, and ovarian cancers (544,545). In combination with other agents, it has also demonstrated activity in early trials of ovarian cancer (546). Vinblastine is the sulfate salt of an alkaloid isolated from *Vinca rosea* (periwinkle). It is structurally related to vincristine, another alkaloid isolated from the same plant. Vinblastine sulfate is a white to off-white crystalline powder that is freely soluble in water, soluble in methane, and slightly soluble in ethanol. Its empiric formula is C₄₆H₅₈N₄O₉ · H₂SO₄, and it has a molecular weight of 909.07.

Mechanism of Action

Vinblastine binds to tubulin and inhibits microtubule assembly. This inhibition prevents mitotic spindle formation and results in an accumulation of cells in metaphase (547).

Vinblastine is considered cell cycle phase specific for mitosis; however, the cytotoxic effect probably occurs in S phase and is expressed only in M phase. At high doses, direct effects may be expressed in S and G₁ phases. Vinblastine is assumed to have stathmokinetic (cell cycle arrest) effects similar to vincristine.

Drug Disposition

After IV administration, vinblastine is rapidly cleared from the plasma and concentrated in various tissues. The apparent volume of distribution for the central compartment is quite large (3 to 4 times the blood volume). Vincristine and vindesine approximate total body water in their distributions. There is a triphasic vinblastine elimination pattern, with average half-lives of 3.7 minutes, 1.6 hours, and 24.8 hours, respectively (548). The drug also localizes in platelet and leukocyte fractions of whole blood (549). A radiolabeled drug study showed that urinary elimination accounts for approximately 33% of the total vinblastine radioactivity, with 21% appearing in the stool, both after 72 hours (549). A large portion of the radiolabel was retained in the body: 73% remained at 6 days after dosing. Apparently, insufficient amounts of the drug pass the blood-brain barrier to produce an effective concentration in the central nervous system. Vinblastine is partially metabolized in the liver. Most of the drug is, therefore, ultimately excreted intact in the bile or the urine. Toxicity may be increased if there is obstructive liver disease, and doses should be greatly reduced.

Administration and Dosage

The solution for administration is usually prepared by adding 10 mL of sodium chloride solution (which may be preserved with phenols or benzyl alcohol) to the 10-mg vial. The use of other solutions is not generally recommended. The resultant solution has a concentration of 1 mg/mL and a pH of 3.5 to 5.0. Solutions prepared with preserved sodium chloride injection may be stored in the refrigerator (protected from light) for 28 days without significant loss of potency.

Vinblastine is usually given by the IV push technique, with the total dose being delivered over approximately 1 minute. This is usually accomplished by slowly pushing the dose through the injection site of a running IV infusion. Alternatively, the drug may be given directly into the vein. If this method is followed, the double-needle technique should be used: do not use the same needle to withdraw the dose from the vial that is used for the direct injection into the vein. Vinblastine is very irritating and should not be given intramuscularly or subcutaneously. Vein patency should be checked before drug administration by flushing with a small quantity of normal saline or D₅W. After the dose has been given, the site should be flushed again to assure that all of the drug has been delivered into the vein.

Vinblastine has been given by several dosing schemes. The dose depends on the protocol being followed, condition of the patient, other drugs or irradiation being used, and individual patient response. Usually, the drug is given no more frequently than once every week. In general, the dosage range is 3.8 to 18.5 mg/m² when used in combination with other agents. Patients are customarily started at a low dose and worked up in 1.8- to 1.9-mg/m² increments, depending on the degree of resulting leukopenia (e.g., the dose should not be increased beyond the dose at which the white cell count reaches 3,000 cells/mm³) (548). The dosage ranges for the indicated use of vinblastine are 6 mg/m² IV on days 1 and 15 as part of the doxorubicin-bleomycin-vinblastine-dacarbazine regimen (Hodgkin's disease) and 0.15 mg/kg IV on days 1 and 2 as part of the cisplatin-vinblastine-bleomycin regimen (testicular cancer) (79). In gynecologic malignancies, vinblastine is only rarely used for ovarian and trophoblastic disease.

Side Effects and Toxicities

The major toxic effect of vinblastine is a dose-related bone marrow depression. This is more frequent and severe than with the close structural analog, vincristine. Dose-related leukopenia occurs with a nadir of 4 to 10 days and with recovery occurring over another 7 to 14 days. Because of the relatively predictable nadir, it may be possible to administer vinblastine cautiously as often as every 7 to 10 days. Thrombocytopenia typically occurs; however, with standard dosing regimens, serious platelet depressions are infrequent. Erythrocytes are usually only slightly depressed.

Nausea and vomiting occur rarely with vinblastine therapy and are at least partially responsive to antiemetics. Severe stomatitis is occasionally observed. Gastrointestinal symptoms, which may be related to neurotoxicity, include constipation, adynamic ileus, and abdominal pain, especially if high doses (>20 mg) are used. These side effects are rarely seen with doses of less than 10 mg. Prophylactic stool softeners may prevent constipation. Generalized muscle and tumor pain are commonly experienced by patients receiving vinblastine, especially in high doses (550).

Neurotoxicity associated with vinblastine occurs less frequently than with vincristine and usually occurs in patients on prolonged therapy or in those receiving high individual doses. Symptoms include paresthesias, peripheral neuropathy, depression, headache, malaise, jaw pain, urinary retention, tachycardia, orthostatic hypotension, or convulsions. Extravasations of vinblastine may result in local soft-tissue necrosis. Treatment with subcutaneously administered hyaluronidase is recommended (278).

Other side effects include a reversible and mild alopecia, rashes, and photosensitivity reactions. Transient hepatitis has also been reported on the continuous-infusion regimen.

There have been several reports of a Raynaud's phenomenon associated with vinblastine or bleomycin in treating testicular cancer. The reaction consists of a delayed presentation of a cold feeling in the hands with physical evidence of cyanosis (551). Ginsberg and coworkers (552) demonstrated a case of vinblastine-associated syndrome of inappropriate antidiuretic hormone (ADH) secretion, which was previously thought to occur only with vincristine.

The drug is well documented as a teratogen in humans, and as with most anticancer drugs, usage in pregnancy is strongly contraindicated (553).

Special Precautions

Avoid extravasation of vinblastine. If extravasation occurs, stop the administration of the remaining drug immediately. Dorr and Alberts (554) favor injection of a corticosteroid into the infiltration site with sodium chloride to dilute the drug. Only minor tissue damage has occurred when vinblastine extravasation was treated with 50 to 500 mg of hydrocortisone sodium succinate. This is followed by cold compresses to minimize spread of the reaction.

Liver disease may alter the elimination of vinblastine and necessitate a dosage reduction. Neurotoxicity may be more frequent in patients with underlying neurologic problems or those who are weak or cachectic at the start of treatment.

Vinblastine solution is topically irritating and has caused corneal irritation when inadvertently splashed in the eyes. Protective precautions should be used by all persons working with the drug.

Vinorelbine

Chemistry

Vinorelbine (Navelbine) is a third-generation semisynthetic vinca alkaloid that has been commercially available in the United States since 1994 for treatment of non-small cell lung cancer. Vinorelbine also appears to have significant activity in breast cancer patients (555,556) and moderate activity in patients with cervical or ovarian cancer (557,558), as well as other tumor types (559). It has a molecular formula of C₄₅H₅₄N₄O₈ · 2C₄H₆O₆ and a molecular weight of 1079.12. Vinorelbine's structure differs from that of the parent compounds, vincristine and vinblastine, in that it contains a nine-member (rather than 8-member) catharanthine ring (560). Its chemical name is 3',4'-didehydro-4'-deoxy-C'-norvincalcoloblastine[R-(R*,R*)-2,3-dihydroxybutanedioate-(1:2)(salt)].

Mechanism of Action

Like other vinca alkaloids, vinorelbine is classified as a "spindle poison" since it interacts with tubulin, with resulting inhibition of microtubule assembly and cellular division during mitosis (561). Vinorelbine blocks cell cycle progression specifically in G₂ and M phases (189).

Drug Disposition

The pharmacokinetics of vinorelbine shows large interpatient variability and is best described by a triphasic model. Following IV administration of a 30-mg/m² dose, a peak plasma level of 1,000 ng/mL is achieved, but the plasma level declines to 100 ng/mL within 2 hours. Vinorelbine rapidly binds to platelets (78% of total dose) and plasma proteins (13.5%), and only 1.7% is available as free drug (561). The drug readily diffuses into other tissues and has a large volume of distribution (75.61 L/kg). The terminal half-life is approximately 45 hours (562).

The primary means of vinorelbine clearance appears to be hepatic metabolism. Approximately 18% and 46% is recovered

in the urine and feces, respectively; however, recovery was incomplete in pharmacokinetic studies (563,564).

Administration and Dosage

Vinorelbine is a vesicant and requires careful administration. The drug should be diluted in a syringe or IV bag to a concentration of 1.5 to 3.0 mg/mL (syringe) or 0.5 to 2 mg/mL (IV bag). When using a syringe or IV bag, vinorelbine should be diluted with dextrose (5%) or sodium chloride (0.9%). When using an IV bag, it may also be diluted with sodium chloride (0.45%), Ringer's injection, or lactated Ringer's injection. Diluted vinorelbine should be administered over 6 to 10 minutes into a side port of a free-flowing IV line closest to the IV bag. Following vinorelbine administration, the vein should be flushed with at least 75 to 125 mL of IV solution. Longer IV infusions (e.g., 20 minutes) are associated with a higher incidence of phlebitis (565).

Vinorelbine solution is incompatible with fluorouracil, mitomycin, and thiotepea. It is also incompatible with several antibiotics (including a number of cephalosporins, amphotericin B, ampicillin, piperacillin, and trimethoprim-sulfamethoxazole), acyclovir, furosemide, ganciclovir, methylprednisolone, and sodium bicarbonate (566).

Vinorelbine is generally administered at a dose of 30 mg/m² every week. This dosing schedule has been used in combination chemotherapeutic regimens; however, the recommended dosing schedule in combination with cisplatin (100 mg/m² every 4 weeks) is weekly administration of vinorelbine at a dose of 25 mg/m². Attempts to increase vinorelbine dose intensity using a daily $\times$ 3 every 21 days dosing schedule with or without G-CSF have not been successful (567,568). However, Weiss et al. (569) reported that continuous infusion of vinorelbine at doses of 8 to 10 mg/m²/day with concurrent administration of G-CSF results in a twofold increase in vinorelbine dose intensity without increasing toxicity.

Side Effects and Toxicities

The primary dose-limiting toxicity of vinorelbine is myelosuppression, chiefly granulocytopenia (36% of patients, <500 cells/mm³). A safety summary of data from North American clinical trials reported that when vinorelbine was administered at a dose of 30 mg/m²/week to patients with breast cancer and non-small cell lung cancer, 64% of patients experienced grades 3 to 4 granulocytopenia, 50% experienced grades 3 to 4 leukopenia, and 9% developed grades 3 to 4 anemia. Despite the high incidence of granulocytopenia, most events were uncomplicated and only 7% of patients required hospitalization for fever and/or infection. The death rate due to sepsis was 1% to 2%. Myelosuppression was noncumulative, and the incidence of grades 3 and 4 granulocytopenia declined during later cycles of vinorelbine therapy. The granulocyte nadir typically occurred on day 14 of treatment, with recovery of the granulocyte count within 7 days (570).

Vinorelbine therapy is frequently associated with transient increases in liver enzymes, especially alkaline phosphatase. Virtually all patients experience a rise in alkaline phosphatase, with approximately 25% developing grade 3 toxicity and an additional 2% experiencing grade 4 elevations. Increases in AST and ALT also occur in more than half of all patients. However, most patients with liver enzyme increases remain asymptomatic and do not require dose modification of vinorelbine. Total bilirubin also can be elevated: 10% of patients experience some degree of increased bilirubin, with 2% experiencing grade 4 elevation. Because of the high incidence of liver and bone metastases in the study population (breast cancer and non-small cell lung cancer patients), the proportion of these toxicities that is directly attributable to vinorelbine therapy is unknown (570).

Other common toxicities associated with vinorelbine when administered as a single agent at a dose of 30 mg/m²/week by a 20-minute IV infusion include nausea (38% overall, 2% severe), vomiting (17% overall, 2% severe), constipation (31%, 3%

severe), asthenia (29%, 5% severe), injection-site reactions (26%, 2% severe), anorexia (15%, 1% severe), diarrhea (15%, 1% severe), stomatitis (14%, 0% severe), pain (13%, 2% severe), paresthesia (13%, $<1\%$ severe), fever (11%, 1% severe), and alopecia (10%, $<1\%$ severe) (570). Vinorelbine-induced nausea and vomiting are generally mild and are readily controlled with standard antiemetic medication (570). Injection-site reactions include erythema, warmth, pain, and phlebitis. Repeated administration of vinorelbine can result in discoloration of the vein. As discussed above, shortening the injection duration to 6 to 10 minutes significantly reduces the incidence of injection-site reactions (565).

Injection-site pain and pain of unspecified etiology has been reported with administration of vinorelbine as a single agent (570). Additionally, acute tumor pain has been reported in several cancer patients who received treatment with vinorelbine plus a platinum-containing agent (either carboplatin or cisplatin) (571,572).

Pulmonary toxicity is an infrequent side effect of vinorelbine. Approximately 5% of patients experience dyspnea. Some cases of dyspnea are characterized by rapid onset during administration and resolve with bronchodilator therapy. Other cases occur usually within 1 hour of vinorelbine infusion and are characterized by life-threatening progressive dyspnea and the development of interstitial infiltrates (570,573). The coadministration of mitomycin may increase the pulmonary toxicity of vinorelbine (573).

Rare side effects of vinorelbine include pancreatitis, PPE (with prolonged infusions), paralytic ileus, and syndrome of inappropriate ADH secretion (574–577).

Special Precautions

Vinorelbine extravasation can result in severe local irritation, tissue necrosis, and phlebitis. If extravasation occurs, the injection should be halted immediately and any remaining portion of the dose should be injected into a different vein. Specific antidotes for vinorelbine extravasation have not been studied; however, vinblastine extravasation reactions may be ameliorated with the use of corticosteroid injections followed by cold compresses (554).

Drug Interactions

In that vinca alkaloids are metabolized by the cytochrome P450 3A system, coadministration of strong P450 inhibitors, such as erythromycin and ketoconazole, could potentially reduce vinorelbine clearance and increase toxicity (578,579). Doxorubicin and etoposide also are metabolized by the P450 system, and coadministration of these drugs with vinorelbine could potentially affect vinorelbine metabolism (578).

Mitomycin is known to exacerbate vinca alkaloid-induced pulmonary toxicity (580), and the combination of high-dose vinorelbine (50 mg/m² on days 1 and 21) plus mitomycin (15 mg/m² on day 1) has been associated with life-threatening acute pulmonary toxicity characterized by rapid onset of severe, progressive dyspnea and the development of bilateral interstitial infiltrates (573).

The combination of paclitaxel and vinorelbine has been associated with severe neurotoxicity including grade 4 motor neuropathy, irreversible ototoxicity, and vocal cord paresis (581,582). In one report of clinical experience in 5 patients with preexisting, mild to moderate, paclitaxel-induced sensory neuropathy, the combination of vinorelbine 25 to 30 mg/m² followed by paclitaxel 150 mg/m² by 3-hour infusion every 2 weeks resulted in severe, slowly reversing motor neuropathy in all 5 patients. Four of the 5 patients required the use of a wheelchair (581).

Special Applications

On a well-tolerated weekly dose schedule for vinorelbine, Bajetta and colleagues (583) noted 4 partial responses and one complete response in 31 patients (24 platinum-resistant, 4 platinum-sensitive, 5 with undetermined sensitivity) for an overall

response rate of 15% (95% CI of 5.1, 37.9%). A phase II trial (vinorelbine 30 mg/m² weekly infusion) in persistent or recurrent ovarian cancer found a 29% objective response rate; granulocytopenia was a dose-limiting but manageable toxicity (557). This is consistent with previous findings of a 21% response rate in the population of heavily pretreated and platinum-resistant ovarian cancer patients (583).

Molecularly Targeted Agents

Estrogen Receptor/Progesterone Receptor-targeted Agents

Anastrozole

Chemistry

Anastrozole (Arimidex) is FDA approved in 3 settings to treat postmenopausal breast cancer: 1) For the adjuvant treatment of postmenopausal patients with estrogen receptor positive (ER+) early breast cancers; 2) For the first-line treatment of postmenopausal women with ER+ or hormone receptor unknown locally advanced or metastatic breast cancer; and 3) For second-line treatment following tamoxifen therapy. It is one of many available aromatase inhibitors (AI) but is unique in that it is a nonsteroidal AI. Anastrozole is rarely associated with response in ER-negative disease. Anastrozole has been shown to have fewer side effects and a significant survival advantage compared to megestrol acetate in the treatment of postmenopausal patients with breast cancer (584). Chemically, it is 1,3-benzenediacetonitrile, α , α , α' , α' -tetramethyl-5-(1H-1,2,4-triazol-1-ylmethyl). It has a molecular formula of C₁₇H₁₉N₅ and a molecular weight of 293.4.

Mechanism of Action

Anastrozole is a nonsteroidal AI that prevents the peripheral conversion of androgens (androstenedione and testosterone) to estrogens (estrone, estrone sulfate, and estradiol) (79). Anastrozole has a significant effect on serum estradiol; as low as 1 mg/day has caused estradiol levels to be undetectable (585). In patients receiving 5 and 10 mg of anastrozole, there was no effect on adrenal corticosteroids or aldosterone.

Drug Disposition

Following oral administration, anastrozole is well absorbed into the systemic circulation and not affected by food ingestion. Pharmacokinetics is linear and not affected by repeated dosing. Steady state concentration levels are achieved after approximately 7 days of treatment.

Administration and Dosage

Anastrozole is administered orally at a dose of 1 mg/day. For advanced disease, treatment should continue until disease progression.

Side Effects and Toxicities

When compared in a controlled clinical study to megestrol acetate, the principal side effect of anastrozole was diarrhea (occurred in 8.4% vs. 2.8% of patients treated with megestrol acetate). In general, it is very well tolerated, with the most frequent side effects (any grade) being asthenia (18%), nausea (18%), headache (14%), hot flashes (13.2%), and pain (10%).

Special Precautions

Anastrozole is contraindicated in pregnancy and premenopausal women as well as those who have shown a hypersensitivity to the drug or its excipients. In women with preexisting ischemic

heart disease, an increased incidence of ischemic cardiovascular events has been seen. It can also cause a decrease in bone mineral density and an elevation in serum cholesterol.

Drug Interactions

Coadministration of anastrozole and tamoxifen in breast cancer patients reduced anastrozole plasma concentrations by 27%. Estrogen-containing regimens should not be coadministered as they may diminish its pharmacologic action. The drug does not appear to alter the effect of warfarin or inhibit cytochrome P450.

Special Applications

According to the National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology for Uterine Neoplasms (586), anastrozole (as well as other AIs) is listed as a possible “substitute” for progestational agents or tamoxifen in treating “asymptomatic or low-grade metastases.” It is hypothesized that anastrozole may play a role on a molecular level in the endometrium. Most endometrial carcinomas are associated with endometrial hyperplasia and are estrogen receptor (ER) and progesterone receptor (PR) positive. In addition to ER/PR status, there is a progressive increase in the expression of the protein pS2 from normal to hyperplastic to well-differentiated carcinoma (587). Aromatase inhibition may alter the course of disease by preventing the endometrium from being exposed to estrogen. This may in turn alter the expression of the pS2 protein as there is a strong association between ER/PR expression and expression of pS2 protein (587). Aromatase activity has been demonstrated in both ER/PR-positive and ER/PR-negative endometrial carcinomas (588). Although much research is still needed, phase I and II trials have demonstrated safety and minimal activity in an unselected population of recurrent endometrial carcinoma patients (589,590). There is some evidence that it may have benefit in the treatment of endometrial hyperplasia as well as endometrial stromal sarcomas (591).

Finally, the NCCN Clinical Practice Guidelines in Oncology for Ovarian Cancer (592) reported mentions anastrozole as well as other “hormonal therapies” (593) as “potentially active.” Case reports have also noted responses in recurrent and metastatic ovarian sex cord stromal cancers such as granulosa cell tumors (594).

Letrozole

Chemistry

Letrozole (Femara) is a nonsteroidal AI that is FDA approved for the adjuvant treatment of postmenopausal women with hormone receptor positive early breast cancer as well as the first- and second-line treatment of advanced or metastatic breast cancer (hormone receptor positive or hormone receptor unknown). Letrozole is also used for the treatment of advanced breast cancer in postmenopausal women whose disease has progressed following antiestrogen therapy. The chemical name of letrozole is 4,4'-(1H-9 1,2,4-Triazol-1-ylmethylene) dibenzonitrile, and the empirical formula is C₁₇H₁₁N₅.

Mechanism of Action

Similar to other AIs, letrozole inhibits the conversion of androgens to estrogens via the aromatase enzyme. Letrozole treatment does not increase serum follicle stimulating hormone (FSH) and as a selective gonadal steroidogenesis inhibitor, does not impact adrenal mineralocorticoid or glucocorticoid synthesis.

Drug Disposition

Letrozole is not affected by food intake, and is rapidly and completely absorbed through the gastrointestinal tract. The terminal

elimination half-life is 2 days. The major excretion route is via the kidneys. Steady-state plasma concentration is reached in 2 to 6 weeks of daily 2.5 mg dosing. These concentrations are up to 2 times higher than after a single dose. Steady state levels can be maintained for long periods of time without continuous accumulation of letrozole.

Administration and Dosage

Letrozole is administered orally at 2.5 mg per day. Letrozole can be taken at any time during the day regardless of food intake. Treatment is indicated until disease progression.

Side Effects and Toxicities

Letrozole has a more favorable toxicity profile compared to tamoxifen, with greater or equivalent efficacy in breast cancer patients (595). The most common side effects (>20%) include hot flashes and arthralgia. Bone pain, flushing, sweating, asthenia, edema, back pain, nausea, hypercholesterolemia, and dyspnea each occur in less than 20% of patients.

Special Precautions

Letrozole may cause a decrease in bone mineral density to a much greater degree than tamoxifen. Increases in serum cholesterol, as well as hepatic impairment, have also been observed with Letrozole. Since it causes fatigue, dizziness and somnolence, caution should be advised when driving or using machinery. Letrozole is contraindicated in pregnancy.

Drug Interactions

Coadministration of letrozole and tamoxifen in breast cancer patients reduced anastrozole plasma concentrations by 38%. Estrogen-containing regimens should not be coadministered as they may diminish its pharmacologic action. The drug does not appear to alter the effect of warfarin or inhibit cytochrome P450.

Special Applications

Like anastrozole, the NCCN Clinical Practice Guidelines in Oncology for Ovarian Cancer (592) mention letrozole along with other “hormonal therapies” (593) as “potentially active (596,597). Finally, the NCCN Clinical Practice Guidelines in Oncology for Uterine Neoplasms (586) lists letrozole (as well as other AIs) as a possible “substitute” for progestational agents or tamoxifen in treating “asymptomatic or low-grade metastases” from endometrioid endometrial cancers.

Medroxyprogesterone

Chemistry

The chemical name of the progestational agent medroxyprogesterone acetate (Provera) is Pregn-4-ene-3,20-dione,17-(acetyloxy)-6-methyl-, (6 α)-. Its empirical formula is C₂₄H₃₄O₄, with a molecular weight of 386.53. Medroxyprogesterone acetate (MPA) therapy is indicated for the treatment of secondary amenorrhea and abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology, such as fibroids or uterine cancer. MPA is also indicated with estrogen therapy for therapeutic use in women to reduce the incidence of endometrial hyperplasia. MPA is not approved as a therapeutic approach to any solid tumor.

Drug Disposition

MPA is absorbed through the gastrointestinal tract and is primarily metabolized by the liver. Maximum concentrations are reached within 2 to 4 hours after oral administration. Food intake enhances the bioavailability of MPA (C_{max} by up to 70%

and AUC up to 33% increase) but does not affect its half-life (12 to 16 hours).

Administration and Dosage

MPA is administered at 5 or 10 mg/day for endometrial hyperplasia for 12 to 14 consecutive days every month. For abnormal uterine bleeding or amenorrhea, MPA is generally administered for a shorter duration (e.g., 5 to 10 consecutive days). Patients experience withdrawal bleeding for 3 to 5 days following the treatment cycle. Medroxyprogesterone acetate is recommended to be used with 0.625 mg conjugated estrogens in women with a uterus to avoid the risk of endometrial cancer. Women without a uterus may receive estrogen without a progestin. In addition to the tablet form for oral intake, there is an intramuscular (IM) depot formulation that may permit alternative treatment regimens. The IM formulation of MPA was compared to oral megestrol acetate for the treatment of menopausal symptoms in breast cancer patients. In this short-term study, the IM formulation provided superior benefit to patients and may be an alternative to long-term oral progestin therapy (598).

Side Effects and Toxicities

Medroxyprogesterone acetate, similar to other progestins (e.g., megestrol acetate), may cause abnormal uterine bleeding, breast tenderness, or nausea. The Women’s Health Initiative (WHI) study found that estrogen plus progesterone was associated with an increased risk of myocardial infarction, stroke, invasive breast cancer, pulmonary emboli, and deep vein thrombosis in postmenopausal women (599). A memory study embedded within the WHI found that this combination may also be associated with an increased risk of developing dementia in women over the age of 65 (600). A black box warning now included on the MPA package insert recommends that estrogen/progesterone be used at the lowest possible dose for shortest duration possible for the specific treatment goals of the patient.

Special Precautions

MPA is almost exclusively metabolized in the liver, with the glucuronide conjugate metabolites being excreted in the urine. Thus, MPA should be used with extreme caution in renal insufficiency or hepatic impairment. MPA is contraindicated in women with undiagnosed genital bleeding, breast cancer, suspected estrogen- or progesterone- dependent neoplasia, active venous or arterial thrombosis, missed abortion, pregnancy, or known hypersensitivity to MPA.

Drug Interactions

No formal pharmacokinetic drug interaction studies of MPA have been performed.

Special Applications

There is some evidence that MPA can be used for endometrial hyperplasia or stage I endometrial cancer as an alternative to surgery to preserve fertility (601,602). Medroxyprogesterone acetate has also demonstrated activity when used with other agents in advanced or recurrent endometrial cancer (603,604). Along with AIs and tamoxifen, MPA and other progestational agents are listed as an option in treating recurrent or advanced endometrial cancer by the NCCN (586). The NCCN does not list MPA as an active agent in epithelial ovarian cancer.

Megestrol Acetate

Chemistry

The chemical name of megestrol acetate (Megace) is 17 α -acetyloxy-6-methylpregna-4,6-diene-3,20-dione. Similar to

MPA, it has the empirical formula $C_{24}H_{34}O_4$, and has a molecular weight of 384.51. Megestrol acetate is an FDA-approved progestin that is used for the palliative treatment of advanced carcinoma of the breast or endometrium (i.e., recurrent, inoperable, or metastatic disease). The precise mechanism by which megestrol acetate produces its antineoplastic effects against endometrial carcinoma is unknown. However, there is evidence to suggest a local effect as a result of the marked changes brought about by the direct instillation of progestational agents into the endometrial cavity. The antineoplastic action of megestrol acetate on carcinoma of the breast is better understood. Progestational agents like megestrol acetate modify the action of other steroid hormones and exert a direct cytotoxic effect on tumor cells. Pharmacologic doses of megestrol acetate not only decrease the number of hormone-dependent human breast cancer cells but also is capable of modifying and abolishing the stimulatory effects of estrogen on these cells. It has been suggested that progestins may inhibit cell growth in one of 2 ways: by interfering with either the stability, availability, or turnover of the estrogen receptor complex in its interaction with genes or in conjunction with the progestin receptor complex, or by interacting directly with the genome to turn off specific estrogen-responsive genes.

Drug Disposition

Megestrol acetate is primarily excreted in the urine, and oral absorption rates are variable. Duration to peak concentration ranges from 1.0 to 3.0 hours, and the plasma elimination half-life ranges from 13.0 to 104.9 hours. Steady state plasma concentrations have not yet been established.

Administration and Dosage

Megestrol acetate is supplied in 20 mg and 40 mg tablets for oral intake. Although the recommended dosage for breast cancer is 160 mg/day (40 mg q.i.d.), and for endometrial carcinoma it is 40 to 320 mg/day in divided doses, there are a wide variety of dose and schedules implemented therapeutically for precancerous conditions (e.g., Atypical Endometrial Hyperplasia [AEH]).

Side Effects and Toxicities

The side effect profiles of the progestational agents such as megestrol acetate or MPA are similar. However, weight gain is a common side effect with megestrol acetate. Thrombophlebitis and pulmonary embolism have been reported with megestrol acetate. Other toxicities include heart failure, nausea and vomiting, edema, breakthrough menstrual bleeding, dyspnea, tumor flare (with or without hypercalcemia), hyperglycemia, glucose intolerance, alopecia, hypertension, carpal tunnel syndrome, mood changes, hot flashes, malaise, asthenia, lethargy, sweating, and rash. In general, severe toxicities with progestational agents are rare.

Special Precautions

Megestrol acetate should be used with caution in patients with a history of thromboembolic disease. Exacerbation of preexisting diabetes with increased insulin requirements has also been reported in association with the use of megestrol acetate.

Drug Interactions

Drug interactions with megestrol acetate have not been evaluated.

Special Applications

In general, progestational agents are currently used in the treatment of endometrial hyperplasia at a variety of doses and schedules. The GOG is currently investigating megestrol

acetate in trial GOG-0224 [A Randomized, Controlled Phase II Evaluation Of Megestrol (Megace®) in Different Dose and Sequence in the Treatment of Endometrial Intraepithelial Neoplasia (EIN) from a Referred Cohort of Atypical Endometrial Hyperplasia or EIN)]. GOG-0224 is designed to provide objective data toward a standard treatment regimen for the care of women with EIN or AEH in addition to understanding the actual mechanism of action of progestational agents in the endometrium.

Megestrol acetate 80 mg BID $\times$ 3 weeks, alternating with tamoxifen 20 mg BID $\times$ 3 weeks orally, has been shown by the GOG to be the most active regimen in treating advanced endometrial carcinoma (605). Among 56 eligible patients, 15 patients responded (12 complete, 3 partial), for an overall response rate of 27% (90% CI: 17% to 38%). In 8 of 15 (53%) responders, response duration exceeded 20 months. The response rate was 38% in patients with histologic grade 1 tumors ($n = 16$), 24% in those with grade 2 disease ($n = 17$), and 22% among patients with grade 3 disease ($n = 23$). Women less than or equal to 60 years ($n = 16$) appeared to have a better response rate than those >60 years ($n = 40$), 44% versus 20%. The response rate in patients with extra pelvic disease ($n = 42$) was 31% compared to 14% in those with strictly pelvic and/or vaginal disease ($n = 14$). The median progression-free survival (PFS) was 2.7 months, and the median overall survival was 14.0 months. Two patients experienced a grade 4 thromboembolic event. Additional toxicities included one of each: grade 3 gastrointestinal, grade 3 neurologic, and grade 3 genitourinary. The NCCN lists megestrol acetate as an active drug in both endometrial carcinoma (586) and epithelial ovarian cancer (606).

Tamoxifen Citrate

Chemistry

Tamoxifen citrate (Nolvadex) is a nonsteroidal agent with antiestrogenic properties. It is indicated for the treatment of metastatic breast cancer in men and women. In premenopausal women, it is an alternative to oophorectomy or ovarian irradiation. ER+ tumors are more likely to respond. Tamoxifen is also indicated as adjuvant treatment in node-positive and -negative breast cancers. Thirdly, it is indicated in women with ductal carcinoma *in situ* (DCIS) to reduce the risk of invasive carcinoma. Finally, it is approved to reduce the incidence of breast cancer among high-risk women. Tamoxifen competes with estrogen for binding sites, which explains its increased effectiveness in ER+ tumors. Chemically, tamoxifen is (Z)-2-[4-(1,2-diphenyl-1-butenyl) phenoxy]-N, N-dimethylethanamine 2-hydroxy-1,2,3-propanetricarboxylate (1:1), and has a molecular weight of 563.62.

Mechanism of Action

Tamoxifen, like raloxifene and toremifene, is a nonsteroidal selective estrogen receptor modulator (SERM). All 3 agents are competitive inhibitors of estrogen binding to ER, and all have mixed agonist and antagonist activity, depending on the target tissue. These mixed activities have led to the redesignation of this class of compounds from “anti-estrogens” to SERMs.

SERMs provide some protection against menopausal bone loss, presumably due to their partial agonist activity. However, the increase in bone density is substantially less than that seen with estrogen. SERMs lowers the serum total and low-density lipoprotein (LDL)-cholesterol concentrations (by 12% and 19%, respectively, in one report), although they do not increase serum HDL-cholesterol. Tamoxifen’s antagonist effect is particularly prominent with respect to breast cancer. Finally, tamoxifen is an estrogen agonist in the endometrium.

Most receptors of the steroid family, with the exception of the ER, are classically viewed as “translocating receptors.” That is, they move from a principally cytoplasmic distribution in the

absence of hormone to a predominantly nuclear localization in hormone-stimulated cells. However, the ER appears to be predominantly nuclear both in the presence and absence of hormone. The ER operates as a ligand-dependent transcription factor; attachment of estrogen hormone to the ER's ligand-binding domain results in either direct binding of the ER to estrogen response elements (EREs) in the promoter of target genes or to a protein-protein interaction with coactivators at their respective promoter sites (607). Subsequently, the hormone-receptor complex is able to bind to estrogen-specific response elements that activate or repress expression of genes whose protein products are responsible for the physiologic actions of the hormone. Estrogen exerts its effect through 2 receptors, ER α and ER β . The exact function of ER α and ER β is under study, but they appear to have different biological functions, as indicated by their distinct expression patterns.

Drug Disposition

Peak plasma concentrations (average 40 ng/mL) take place approximately 5 hours after dosing. The decline in plasma concentrations is biphasic, with a terminal elimination half-life of about 6 days. Steady-state concentrations for tamoxifen are achieved in approximately 4 weeks after initiation of therapy. Tamoxifen is extensively metabolized, with N-desmethyl tamoxifen being the major metabolite. Approximately 65% of the administered dose is eliminated in the feces within 2 weeks (608).

Administration and Dosage

Tamoxifen is available in 10- and 20-mg tablets for oral administration. The recommended dosage is 20 to 40 mg/day; when the higher daily dose is prescribed, it should be divided into 2 doses of 20 mg (morning and evening).

Side Effects and Toxicities

Tamoxifen causes estrogenic changes of the vaginal and cervical squamous epithelium and increases the incidence of cervical and endometrial polyps (609). It is associated with an increased risk of uterine malignancies (endometrial adenocarcinoma and uterine sarcoma). Other serious adverse events associated with tamoxifen treatment include stroke, deep vein thrombosis, and pulmonary embolism. A discussion weighing the benefits versus the risks should take place prior to treatment with tamoxifen; however, the benefits have been determined to outweigh the risks in women who take tamoxifen to reduce the risk of breast cancer recurrence. The National Adjuvant Breast and Bowel Project (NSABP P-1) found a higher incidence of the following side effects for tamoxifen versus placebo, respectively: vaginal discharge (54.7 vs. 34%); cold sweats (21.4% vs. 14.8%); hot flashes (77.7% vs. 65.1%); night sweats (66.8% vs. 54.9%); and genital itching (47.1% vs. 38.3%) (610). Serious adverse events reported more frequently among women taking tamoxifen compared to placebo in the NSABP P-1 trial included uterine malignancy, uterine sarcoma, stroke, and pulmonary embolism.

Special Precautions

Tamoxifen is contraindicated in patients with known hypersensitivity to the drug or any of its ingredients. In the treatment of DCIS, tamoxifen is contraindicated in women who require concomitant anticoagulant therapy or in women with a history of deep-vein thrombosis or pulmonary embolus. As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastases within a few weeks of starting treatment with tamoxifen. Tamoxifen has been associated with changes in liver enzyme levels, and on rare occasions, a spectrum of

more severe liver abnormalities including fatty liver, cholestasis, hepatitis, and hepatic necrosis. Ocular disturbances, including corneal changes, decrement in color vision perception, retinal vein thrombosis, and retinopathy have been reported in patients receiving tamoxifen. An increased incidence of cataracts and the need for cataract surgery have been reported in patients receiving tamoxifen.

Drug Interactions

When tamoxifen is used in combination with coumarin-type anticoagulants, a significant increase in anticoagulant effect may occur.

Special Applications

Some ovarian cancers express hormonal receptors, a factor supporting the investigation of tamoxifen in the treatment of ovarian malignancies (611). It has demonstrated activity in patients with platinum-refractory ovarian cancer, with response rates ranging from 13% to 17% (with some complete responses), and with durations ranging from 4.4 months to more than 5 years (611–614). In the series by Hatch and colleagues (611), patients with ovarian cancer who had complete or partial responses on tamoxifen were more likely to have an ER+ tumor (89% ER+) than those who had stable disease or progression on tamoxifen (59% had elevated ER). The favorable toxicity profile of tamoxifen makes it an ideal agent to consider in patients with refractory ovarian cancer. In addition to activity in ovarian cancer, the NCCN also lists tamoxifen as an active agent in endometrial cancer (586).

Leuprolide Acetate

Chemistry

Leuprolide acetate (Lupron) is a synthetic nonapeptide analog of naturally occurring gonadotropin-releasing hormone (GnRH), also known as Luteinizing-hormone-releasing hormone (LHRH). The analog possesses greater potency than the natural hormone. It indicated in the palliative treatment of advanced prostate cancer. The chemical name is 5-oxo-L-prolyl-L-histidyl-L-tryptophyl-L-seryl-L-tyrosyl-D-leucyl-L-leucyl-L-arginyl-N-ethyl-L-prolinamideacetate. GnRH agonists are synthetically modeled after the natural GnRH decapeptide, with specific amino acid substitutions typically in positions 6 and 10. Other than leuprolide acetate, other agonists include: (a) Buserelin (Suprefact, Supreacor); (b) Nafarelin (Synarel) (only a single substitution at position 6); (c) Histrelin (Supprelin LA, Vantas); (d) Goserelin (Zoladex); and (e) Deslorelin (Suprelorin, Ovuplant). These medications can be administered intranasally, by injection, or by implant. Injectables have been formulated for daily, monthly, and quarterly use, and implants can last from 1 to 12 months.

Mechanism of Action

GnRH agonists do not quickly dissociate from the GnRH receptor. As a result, initially there is an increase in FSH and LH secretion (so-called “flare effect”). However after approximately 10 days a profound hypogonadal effect (i.e., decrease in FSH and LH) is achieved through receptor down-regulation by internalization of receptors. Generally, this induced and reversible hypogonadism is the therapeutic goal.

Drug Disposition

Following a single injection of 7.5 mg of leuprolide acetate (depot Lupron), the mean plasma leuprolide concentration is almost 20 ng/mL at 4 hours and 0.36 ng/mL at 4 weeks. The mean steady-state volume of distribution of leuprolide following IV bolus administration to healthy male volunteers was 27 L.

In vitro binding to human plasma proteins ranged from 43% to 49%. In healthy male volunteers, a 1-mg bolus of leuprolide administered IV revealed that the mean systemic clearance was 7.6 L/h, with a terminal elimination half-life of approximately 3 hours based on a 2-compartment model. Following administration of depot Lupron 3.75 mg to 3 patients, less than 5% of the dose was recovered as parent or one of its major metabolites in the urine.

Administration and Dosage

The recommended dose of depot Lupron has traditionally been 7.5 mg monthly. Other recently approved doses and schedules include 22.5 mg every 3 months, 30 mg every 4 months, and 45 mg every 6 months.

Side Effects and Toxicity

Side effects of GnRH agonists are signs and symptoms of hypogonadism, including hot flashes, headaches, and osteoporosis.

Special Precautions

Leuprolide acetate is contraindicated in individuals with known hypersensitivity to GnRH agonists or any of the excipients in Lupron. Reports of anaphylactic reactions to GnRH agonist analogs have been reported in the medical literature. Leuprolide acetate and other GnRH analogs may cause fetal harm when administered to a pregnant woman. GnRH analogs are contraindicated in women who are or may become pregnant. Hyperglycemia and an increased risk of developing diabetes have been reported in men receiving GnRH agonists. Increased risk of developing myocardial infarction, sudden cardiac death, and stroke has been reported in association with use of GnRH agonists in men.

Drug Interactions

No pharmacokinetic-based drug-drug interaction studies have been conducted with GnRH agonists. However, because leuprolide acetate is a peptide that is primarily degraded by peptidase and not by Cytochrome P-450 enzymes as noted in specific studies, and the drug is only approximately 46% bound to plasma proteins, drug interactions are not expected.

Special Applications

In gynecologic cancers, leuprolide acetate is listed as an active agent in endometrial cancer by the NCCN (586), although the results of clinical trials have been mixed (615,616).

Approximately 80% of human ovarian and endometrial cancers and 50% of breast cancers express GnRH and its receptor as part of an autocrine regulatory system (617). The classical GnRH receptor signal-transduction mechanisms, known to operate in the pituitary, are not involved in the mediation of antiproliferative effects of GnRH analogs in these cancer cells. The GnRH receptor rather interacts with the mitogenic signal transduction of growth-factor receptors and related oncogene products associated with tyrosine kinase activity via activation of a phosphotyrosine phosphatase, resulting in downregulation of cancer cell proliferation. In addition, GnRH activates nucleus factor kappaB (NFkappaB) and protects the cancer cells from apoptosis. Furthermore, GnRH induces activation of the c-Jun N-terminal kinase/activator protein-1 (JNK/AP-1) pathway independent of the known AP-1 activators, protein kinase (PKC), or mitogen activated protein kinase (MAPK/ERK) (618).

Antiangiogenesis Agents

Angiogenesis is the process by which new blood vessels are sprouted from preexisting ones. Endothelial cells must migrate,

proliferate, and assemble into tubes during this process. In normal tissues, blood vessel growth is tightly controlled by numerous angiogenesis-stimulating factors and angiogenesis-inhibiting factors. Vascular endothelial growth factor (VEGF), angiopoietin, and platelet-derived endothelial-cell growth factor (PD-ECGF) are 3 of the most extensively studied growth factors that appear to function primarily as angiogenesis-stimulating factors. Other growth factors and cytokines, such as basic fibroblast growth factor (bFGF), have multiple functions in addition to angiogenesis stimulation (619). Naturally occurring factors that suppress angiogenesis include angiostatin, endostatin, interferon- α , interferon- β , interferon- γ , interleukin-1, interleukin-12, platelet factor-4, thrombospondin-1, 1,2-methoxyestradiol, tissue inhibitor metalloproteinases (TIMPs), and, at high concentrations, tumor necrosis factor- α (620,621).

In the early 1970s, Folkman (622) pioneered the study of tumor angiogenesis with his observation that the growth of tumor nodules to a diameter of greater than 1 to 2 mm required neovascularization of the tumor. He hypothesized that pharmacologic suppression of tumor angiogenesis could induce tumor dormancy. Further research has shown that formation of new blood vessels within tumor nodules results in an exponential increase in tumor cell growth, the transition from hyperplasia to malignancy parallels the induction of neovascularization, and tumor angiogenesis is a prerequisite for metastatic spread (619,623–625). Additionally, blood vessel density of tumors has been shown to be a potentially important prognostic factor in multiple human neoplasms, including cancers of the ovary, cervix, and endometrium (626–630).

Obviously, this is a very brief discussion of tumor angiogenesis. The reader is referred to several reviews on angiogenesis inhibition and its potential for cancer treatment (620,631–636). Several angiogenetic agents have received FDA approval for various indications and may also have potential activity in the treatment of gynecologic cancers. However, only bevacizumab has shown clear clinical benefit. The NCCN lists it as an active agent in recurrent cervical, ovarian, and endometrial cancers (586). In addition, 2 recently reported phase III trials (637,638) have led to regulatory approval of bevacizumab in the front-line treatment of ovarian cancer in many parts of the world, although it has not yet been submitted to the FDA.

Bevacizumab

Chemistry

Bevacizumab (Avastin) is a recombinant humanized monoclonal IgG1 antibody that is designed to inhibit angiogenesis through targeting the human vascular endothelial growth factor (VEGF). Bevacizumab is FDA approved for treatment for first- or second-line metastatic colorectal cancer in combination with 5-FU-based chemotherapy; for first-line treatment of unresectable, locally advanced, recurrent or metastatic nonsquamous non-small cell lung cancer (NSCLC) with carboplatin and paclitaxel; for treatment of glioblastoma with progressive disease following front-line therapy; and for treatment of metastatic renal cell carcinoma with interferon- α . Ovarian, endometrial, and cervical cancers have been shown to express VEGF-A (639–642). Early trials showed promising results in refractory ovarian cancer and heavily pretreated cervical cancer patients (643–645). In addition to the 2 large randomized trials demonstrating efficacy in frontline ovarian cancer mentioned above, a study in platinum-sensitive disease in combination with carboplatin and gemcitabine also met its primary endpoint of improving time to progression (646) (HR, 0.484; 95% CI, 0.388 to 0.605; log-rank $p < 0.0001$).

Mechanism of Action

The immediate mechanism of action of bevacizumab is to bind and inactivate VEGF, thereby inhibiting endothelial cell activation

and proliferation. Bevacizumab contains human framework regions and the complementarity-determining regions of a murine antibody that binds to VEGF. Bevacizumab has an approximate molecular weight of 149 kDa. Bevacizumab is produced in a mammalian cell (Chinese Hamster Ovary) expression system in a nutrient medium containing the antibiotic gentamicin. Gentamicin is not detectable in the final product.

Though the inhibition of tumor angiogenesis was originally thought to simply deny a tumor nutrients and oxygen, VEGF inhibition has also been shown to induce so-called vascular normalization, a restoration of normal structure, function, and flow to the disorganized, leaky vessels characteristic of malignant tumors, which improves the delivery of oxygen, nutrients, and cytotoxic chemotherapy to the tumor. Because VEGF also plays an important role in normal physiologic processes—such as fetal development, stabilization of damaged endothelia, and wound healing—VEGF inhibition carries a unique toxicity profile that involves normal tissues, tumor tissues, and the interface of them both. Despite uncertainty regarding these toxicities, the need for novel antitumor agents was an overriding force for the clinical investigation of bevacizumab.

Drug Disposition

According to the package insert, “The pharmacokinetic profile of bevacizumab was assessed using an assay that measures total serum bevacizumab concentrations (i.e., the assay did not distinguish between free bevacizumab and bevacizumab bound to VEGF ligand). Based on a population pharmacokinetic analysis of 491 patients who received 1 to 20 mg/kg of bevacizumab weekly, every 2 weeks, or every 3 weeks, the estimated half-life of bevacizumab was approximately 20 days (range 11 to 50 days). The predicted time to reach steady state was 100 days. The accumulation ratio following a dose of 10 mg/kg of bevacizumab every 2 weeks was 2.8. The clearance of bevacizumab varied depending on body weight, gender, and tumor burden. After correcting for body weight, males had a higher bevacizumab clearance (0.262 L/day vs. 0.207 L/day) and a larger V_c (3.25 L vs. 2.66 L) than females. Patients with higher tumor burden (at or above median value of tumor surface area) had a higher bevacizumab clearance (0.249 L/day vs. 0.199 L/day) than patients with tumor burdens below the median. There has been no evidence of lesser efficacy (hazard ratio for overall survival) in males or patients with higher tumor burden treated with bevacizumab as compared to females and patients with low tumor burden. The relationship between bevacizumab exposure and clinical outcomes has not been explored.”

Administration and Dosage

Bevacizumab is usually administered in gynecologic cancers at 15 mg/kg IV once every 21 days until disease progression or unacceptable toxicity. However, ICON7 (638) also showed activity of 7.5 mg/kg IV once every 21 days, and 28-day regimens generally use 10 mg/kg IV once every 14 days.

Side Effects and Toxicities

The most common serious (grade 3 to 4) side effects of bevacizumab treatment include asthenia, pain, hypertension, diarrhea, and leucopenia. Bevacizumab has been associated with gastrointestinal perforation (647), wound healing complications, and hemorrhage. Hemorrhage was specifically pronounced among patients with recent hemoptysis; therefore, these patients should not receive bevacizumab. Patients receiving bevacizumab therapy have also demonstrated an increase in hypertension, proteinuria, and congestive heart failure. It is recommended that bevacizumab therapy be delayed at least 28 days following any major surgical procedure. The safety of bevacizumab in patients with cardiovascular disease is limited. The management of

bevacizumab-associated toxicities in ovarian cancer have been recently reviewed by Randall and Monk (648).

Special Precautions

The warnings and precautions include the following:

- Nongastrointestinal fistula formation: Discontinue bevacizumab if fistula formation occurs.
- Arterial thromboembolic events (ATE) (e.g., myocardial infarction, cerebral infarction): Discontinue bevacizumab for severe ATEs.
- Hypertension: Monitor blood pressure and treat hypertension. Temporarily suspend bevacizumab if not medically controlled. Discontinue bevacizumab for hypertensive crisis or hypertensive encephalopathy.
- Reversible posterior leukoencephalopathy syndrome (RPLS): Discontinue bevacizumab.
- Proteinuria: Monitor urine protein. Discontinue for nephrotic syndrome. Temporarily suspend bevacizumab for moderate proteinuria.
- Infusion reactions: Stop for severe infusion reactions.
- Ovarian failure: Inform females of reproductive potential of the risk of ovarian failure with bevacizumab.

Drug Interactions

A drug interaction study was performed in which irinotecan was administered as part of the FOLFIRI regimen with or without bevacizumab. The results demonstrated no significant effect of bevacizumab on the pharmacokinetics of irinotecan or its active metabolite SN38. In a randomized study in 99 patients with NSCLC, based on limited data, there did not appear to be a difference in the mean exposure of either carboplatin or paclitaxel when each was administered alone or in combination with bevacizumab. However, 3 of the 8 patients receiving Avastin plus paclitaxel/carboplatin had substantially lower paclitaxel exposure after 4 cycles of treatment (at day 63) than those at day 0, while patients receiving paclitaxel/carboplatin without bevacizumab had a greater paclitaxel exposure at day 63 than at day 0.

Finally, there was no difference in the mean exposure of interferon alfa administered in combination with bevacizumab when compared to interferon alfa alone.

Special Applications

Bevacizumab has clear clinical activity in ovarian, endometrial, and cervical cancers. However, anti-angiogenesis agents have also been noted to control symptomatic effusions such as malignant ascites (649) and pleural effusions (650). In fact, one case report noted the use of bevacizumab in a woman with refractory ovarian granulosa-cell carcinoma and symptomatic ascites (651).

MODULATING AGENTS/ SUPPORTIVE CARE DRUGS USED IN THE TREATMENT OF GYNECOLOGIC CANCERS

Defining approaches to improve the therapeutic index of cancer chemotherapy, such that tumor-cell kill is enhanced while toxicity to normal cells is minimized, remains a fundamental goal of cancer treatment. A major limiting factor in successful cancer therapy is the ability of the tumor to develop resistance to the drugs used for treatment. A second fundamental problem faced by the oncologist treating patients with chemotherapy is the acute and chronic toxic effects of the drugs to the normal tissues.

One approach that holds promise for the improvement of the therapeutic index is the concept of modulation, or the use of drugs with little or no cytotoxic activity to modulate the efficacy of standard anticancer drugs. Modulating agents can be divided into 3 main classes based on their ability to: (a) protect host tissue from the toxic effects of the cancer drugs; (b) potentiate anticancer drugs; and (c) reverse acquired drug resistance. In this section, we discuss agents with chemoprotective abilities used with chemotherapy in the treatment of gynecologic cancers. Agents such as erythropoiesis-stimulating agents and myeloid growth factors are discussed elsewhere. Amifostine (652) and dexrazoxane (653) are not commonly used agents in gynecologic oncology and are thus not considered.

Chemoprotective Agents

Leucovorin

Chemistry

Leucovorin, a chemically reduced derivative of folic acid, is also known as citrovorum factor or folinic acid. It was the original chemoprotective agent employed to overcome high-dose methotrexate-induced bone marrow toxicity (654,655). Leucovorin calcium tablets contain either 5 mg or 25 mg leucovorin as the calcium salt of N-[4-[(2-amino-5-formyl-1, 4, 5, 6, 7, 8-hexahydro-4-oxo-6-pteridiny]methyl] amino]benzoyl]-L-glutamic acid.

Mechanism of Action

Leucovorin can serve as a substitute for the endogenous reduced-folate cofactor (N^5 , N^{10} -methylene tetrahydrofolate) that is diminished by methotrexate. Thus, leucovorin can “rescue” cells by replenishing intracellular reduced-folate pools and preventing methotrexate toxicity via blockade of thymidine synthesis. Leucovorin acts in a dose- and time-dependent fashion and must be given within 48 hours of methotrexate in order to elicit its rescue effects.

Leucovorin is also a successful modulatory agent used clinically to potentiate the antitumor activity of 5-FU (656). Leucovorin can enhance the DNA toxicity induced by 5-FU through the formation of a stable tertiary complex of 5,10-methylene tetrahydrofolate, thymidylate synthase, and fluorodeoxyuridine monophosphate. Compared with 5-FU alone, this combination has been shown to produce higher response rates and, in some cases, longer survival for patients with metastatic gastrointestinal malignancies (657). The combination of 5-FU and leucovorin currently is being tested extensively in other malignancies, including metastatic breast cancer (658). A complete review of leucovorin as a modulating agent is beyond the scope of this chapter, and the reader is referred to a number of excellent reviews on this topic (656,659).

Drug Disposition

Both IV and intramuscular leucovorin produce rapid increases in serum concentrations of biologically active folates; these rises are sustained over time and are still detectable at 24 hours after drug administration. The bioavailability of IV and intramuscular doses are comparable based on area under the serum concentration-time curve, although for intramuscular administration, the peak concentration was lower and the time to peak concentration is longer. The initial rise in serum folate associated with IV and intramuscular dosing is represented as 5-formyltetrahydrofolate; this falls concomitantly with the appearance of 5-methyltetrahydrofolate. Oral leucovorin is 92% bioavailable compared with IV administration and produces a predictably different pattern of circulating folates, 5-methyltetrahydrofolate being the predominant form. Terminal

elimination half-life, apparent volume of distribution, and clearance of total folate were not significantly different among the 3 treatments.

Administration and Dosage

Leucovorin calcium rescue is indicated after high-dose methotrexate therapy in osteosarcoma. Leucovorin calcium is also indicated to diminish the toxicity and counteract the effects of impaired methotrexate elimination and of inadvertent overdoses of folic acid antagonists.

Leucovorin calcium is indicated in the treatment of megaloblastic anemias due to folic acid deficiency when oral therapy is not feasible. Leucovorin is also indicated for use in combination with 5-fluorouracil to prolong survival in the palliative treatment of patients with advanced colorectal cancer. In advanced colorectal cancer, either of the following 2 regimens is recommended:

1. Leucovorin administered at 200 mg/m² by slow IV injection over a minimum of 3 minutes, followed by 5-fluorouracil at 370 mg/m² by IV injection.
2. Leucovorin administered at 20 mg/m² by IV injection followed by 5-fluorouracil at 425 mg/m² by IV injection. 5-Fluorouracil and leucovorin should be administered separately to avoid the formation of a precipitate. Treatment is repeated daily for 5 days. This 5-day treatment course may be repeated at 4-week (28-day) intervals for 2 courses and then repeated at 4- to 5-week (28 to 35 day) intervals provided that the patient has completely recovered from the toxic effects of the prior treatment course. In subsequent treatment courses, the dosage of 5-fluorouracil should be adjusted based on patient tolerance of the prior treatment course. The daily dosage of 5-fluorouracil should be reduced by 20% for patients who experienced moderate hematologic or gastrointestinal toxicity in the prior treatment course, and by 30% for patients who experienced severe toxicity.

Leucovorin calcium tablets are indicated to diminish the toxicity and counteract the effects of impaired methotrexate elimination and of inadvertent overdoses of folic acid antagonists. Because absorption is saturable, oral administration of daily doses greater than 25 mg is not recommended.

Side Effects and Toxicity

Allergic sensitization, including anaphylactoid reactions and urticaria, has been reported following administration of both oral and parenteral leucovorin. No other adverse reactions have been attributed to the use of leucovorin *per se*.

Special Precautions

Parenteral administration is preferable to oral dosing if there is a possibility that the patient may vomit or not absorb the leucovorin. Leucovorin has no effect on other established toxicities of methotrexate such as the nephrotoxicity resulting from drug and/or metabolite precipitation in the kidney.

Drug Interactions

Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children.

Preliminary animal and human studies have shown that small quantities of systemically administered leucovorin enter CSF primarily as 5-methyltetrahydrofolate and, in humans, remain 1 to 3 orders of magnitude lower than usual methotrexate concentrations following intrathecal administration. However, high doses of leucovorin may reduce the efficacy of intrathecally administered methotrexate. Leucovorin may enhance the toxicity of fluorouracil.

Special Applications

In gynecologic cancer, leucovorin is primarily used with high-dose methotrexate for gestational trophoblastic disease (660–662).

Mesna

Mesna (Mesnex) is used clinically as a specific chemoprotective agent against bladder toxicity resulting from oxazophosphorine-based alkylating agents, such as cyclophosphamide and ifosfamide. It is sodium-2-mercaptoethane sulfonate, with the molecular formula $C_2H_5NaO_3S_2$ and a molecular weight of 164.18.

Mechanism of Action

Mesna inactivates the protein-reactive aldehyde, acrolein metabolite of ifosfamide and cyclophosphamide, which accumulates in the urinary bladder and results in dose-limiting urotoxicity (325). Plasma conversion of mesna to its inactive disulfide metabolite, dimesna, allows for the pretreatment and simultaneous administration of mesna as a urinary protector for ifosfamide and cyclophosphamide (high dose). Following renal filtration and secretion, dimesna is converted back to the active parent compound by glutathione reductase, which is subsequently delivered to the bladder. The mesna free sulfhydryl groups in the urinary bladder can directly complex to and thus neutralize acrolein, in addition to potentially blocking acrolein formation in the urinary tract (663). The metabolic characteristic of mesna should preclude any potential protection to tumors. Indeed, there is no clinical evidence that mesna coadministration with ifosfamide results in decreased antitumor activity. However, mesna has been shown to prevent the cytotoxicity of platinum agents when given simultaneously with them in *in vitro* models. As such, careful scheduling of mesna is warranted for clinical trials using ifosfamide in combination with platinum compounds. Additionally, mesna should not be given simultaneously with cisplatin.

Drug Disposition

Proper scheduling of mesna has been based on pharmacokinetic analysis, which showed that mesna and dimesna have relatively short half-lives of approximately 1 hour and that peak urinary thiol accumulation following IV or oral mesna occurs at 1 and 3 hours, respectively (664). Because the half-life of mesna is much shorter than that of acrolein, it must be administered beyond the completion of ifosfamide.

Administration and Dosage

Mesna is available for IV bolus injection (100 mg/mL) or for oral use, available as 400-mg tablets. For IV administration, it should be diluted to obtain a final concentration of 20 mg/mL. The diluted solution is stable for 24 hours at room temperature. The approved schedule for IV administration of mesna is as a bolus dose (20% of the ifosfamide dose) prior to ifosfamide and 2 additional doses 4 and 8 hours after ifosfamide treatment (390). A combination of IV and oral mesna has been used to simplify outpatient ifosfamide therapy. The oral dose of mesna is given equal to 40% of the ifosfamide dosage in 2 doses at 2 and 6 hours after ifosfamide administration, based on a 50% urinary bioavailability of oral mesna. Oral doses of 3 g/m² have been well tolerated in patients; however, nausea was observed in healthy volunteers receiving oral doses greater than 2 g/m². Goren (665) reviewed the dosing schedules and incidence of hematuria in 47 clinical studies in which oral mesna was administered to 1,986 patients who received more than 6,475 courses of ifosfamide. Compilation of the data showed that a variety of doses and schedules of oral and IV mesna were effective at preventing hemorrhagic cystitis in patients treated with a number of different ifosfamide regimens. Although an optimal dose and schedule of mesna has not been established, adequate protection

against ifosfamide-induced cystitis can be achieved using an initial IV dose of mesna that is equal to 20% of the ifosfamide dose, followed by 2 oral doses of mesna, each equal to 40% of the ifosfamide dose.

Side Effects and Toxicities

The most common side effects of mesna include headache, injection site reactions, flushing, dizziness, nausea, vomiting, flu-like symptoms, and coughing. Patients may develop hematuria (up to 6%) when administered ifosfamide plus mesna; a urine sample should be evaluated for hematuria each day prior to ifosfamide therapy.

Special Precautions

Health care providers should advise patients taking mesna to drink at least a quart of liquid a day. Patients should be informed to report if their urine has turned a pink or red color, if they vomit within 2 hours of taking oral mesna, or if they miss a dose of oral mesna.

Drug Interactions

No clinical drug studies have been conducted.

Special Applications

The superiority of mesna as a chemoprotectant against ifosfamide- and cyclophosphamide-induced bladder toxicity has been demonstrated in a number of clinical trials (390). In a comparative study of patients treated with ifosfamide at a dose of 2 g/m²/day for 5 days, only 20% of the patients treated with mesna (400 mg/m²) exhibited hematuria compared with 60% of those treated with N-acetylcysteine (NAC, 1.5 g/m²) (665). Similar results were reported by Munshi et al. (605), wherein 4.2% of patients treated with mesna developed hematuria compared with 27.9% of NAC patients. In a phase II trial of ifosfamide and mesna in patients with platinum/paclitaxel-refractory ovarian cancer, there were no documented episodes of hemorrhagic cystitis, but one patient experienced treatment-related microscopic hematuria (389).

Subcutaneous administration of mesna is also being explored as an alternative to IV and oral dosing (666). Patients with gynecologic cancers receiving ifosfamide were treated with an initial IV dose of mesna at 20% of the ifosfamide dose. A subcutaneous infusion of mesna was given approximately 30 minutes after the completion of the ifosfamide infusion. A total dose of mesna equal to 40% of the ifosfamide dose was infused at a rate of 4 mL/hr over 8 hours. The subcutaneous infusion of mesna was well tolerated, and no episodes of gross hematuria were observed.

Oprelvekin

Chemistry

Oprelvekin (Neumega) is FDA approved for the prevention of severe thrombocytopenia and to reduce the need for platelet transfusions in patients with nonmyeloid malignancies. The active ingredient is produced from *Escherichia coli* (*E. coli*) by recombinant DNA technology. This protein has a molecular mass of 19,000 daltons and is similar to native interleukin eleven (IL-11) with the exception of its lack of the amino-terminal proline residue.

Mechanism of Action

Interleukin eleven is a thrombopoietic growth factor that induces megakaryocyte maturation, resulting in increased platelet production. Platelets that develop as a result of oprelvekin therapy are morphologically and functionally similar to those produced normally.

Dosage and Administration

Oprelvekin is administered subcutaneously (to the abdomen, thigh, hip, or upper arm) at a dose of 50 $\mu\text{g/kg}$ daily. Patients with renal impairment (creatinine clearance less than 30 mL/min) should receive half the normal dose (e.g., 25 $\mu\text{g/kg}$ daily). Oprelvekin should be initiated within 24 hours of the completion of chemotherapy until the patient's platelet count is at least 50,000/ μL . Treatment generally lasts between 10 and 21 days, and is not recommended beyond 21 days.

Side Effects and Toxicities

Allergic reactions may occur with oprelvekin, and patients should be counseled to be aware of potential allergic symptoms. Treatment with oprelvekin may also cause severe fluid retention. Fluid balance should be monitored during treatment. Other serious adverse effects associated with oprelvekin treatment include cardiovascular events and anemia.

Special Precautions

In the postmarketing setting, oprelvekin has caused allergic or hypersensitivity reactions.

Drug Interactions

Most patients in trials evaluating oprelvekin were treated concomitantly with filgrastim (G-CSF) with no adverse effect of oprelvekin on the activity of G-CSF. No information is available on the clinical use of sargramostim (GM-CSF) with oprelvekin in human subjects.

Special Applications

The primary use of oprelvekin in gynecologic cancer is in the prevention of severe thrombocytopenia and the reduction of the need for platelet transfusions following myelosuppressive chemotherapy. Efficacy has been demonstrated in patients who have experienced severe thrombocytopenia following the previous chemotherapy cycle. Oprelvekin should only be used when the value of chemotherapy dose intensity is clear since dose reduction is another effective strategy of reducing thrombocytopenia in subsequent chemotherapy cycles.

Inhibitors of poly(ADP-ribose) polymerase

Introduction

Poly(ADP-ribose)polymerase-1 (PARP-1) is an enzyme that has several biological roles, one of the most important being its role in the repair of DNA single-strand breaks. There are 17 isoforms of PARP. PARP-2 has a similar function to PARP-1. Tankyrases, involved in telomerase activity, are also PARP isoforms. The functions of many of the isoforms are incompletely understood. All of the PARP inhibitors in development have been designed as inhibitors of PARP-1, although they cross-react to varying degrees with other PARP family members (667).

PARP-1 is activated by DNA single-strand breaks. It uses NAD as a substrate and forms polymers of ADP-ribose attached to histone proteins. These are negatively charged and displace the histone proteins from the DNA backbone, permitting access for specific repair enzymes (668). PARP-1 inhibitors therefore inhibit single-strand break repair and thus have potential applications in cancer therapy. Firstly, they may potentiate the activity of drugs that act by causing DNA damage, and secondly, they have activity as single agents in tumors with specific DNA repair defects.

No PARP inhibitors are currently licensed at the time of writing. However, at least nine have been studied in clinical trials

and several are advanced in clinical development and are showing significant activity in ovarian cancers arising in *BRCA1* and *BRCA2* mutation carriers.

Chemistry

All the PARP inhibitors currently in clinical development mimic the nicotinamide moiety of NAD. A common structural feature retains the 3-carboxamide substituent of the benzamide portion of the molecule in the *sin* configuration, which is optimal for binding to the active site (669). Compounds currently in clinical development include olaparib, veliparib, rucaparib, and BMN 673. Another compound, iniparib, showed early promise in a randomized phase II trial in triple negative breast cancer (670). However, this result was not confirmed in a subsequent phase III study (671). Although this compound seems to have some activity, both anecdotally in *BRCA*-related pancreatic cancer (672) and on subset analysis in combination in triple negatives breast cancer (673), it seems that it is probably not acting as a PARP inhibitor (674,675) and is therefore not included in the following discussion.

Mechanism of Action

There are 2 potential mechanisms of action of PARP inhibitors. They may be used in combination with DNA damaging agents (drugs or radiotherapy) to potentiate their effects or they may be used as single agents in patients whose tumors are deficient in the ability to undertake homologous recombination repair.

In experimental systems, PARP inhibitors have been shown in particular to potentiate monofunctional alkylating agents and topoisomerase I inhibitors (676). Also, they are effective at potentiating radiotherapy (677).

The role of PARP inhibitors that has generated the most interest is in their single-agent activity in familial breast and ovarian cancers. Two simultaneous publications from independent research groups showed that cell lines with a homozygous deletion of *BRCA1* (678) or *BRCA2* (678,679) were exquisitely sensitive to PARP inhibitors. The IC₅₀s for the lines with a homozygous deletion were hundreds to thousands of times lower than the IC₅₀s for the heterozygote or wild-type. Since *BRCA1*- and *BRCA2*-related cancers arising in mutation carriers have lost the function of both alleles of the relevant gene, while their normal tissues are heterozygous, this suggests that PARP inhibitors should show therapeutic activity in this setting.

The selective toxicity towards the *BRCA*-nonfunctional tumors is due to a phenomenon known as selective lethality, whereby 2 individual biochemical lesions will not be individually toxic, but the combination is lethal to the cell. The *BRCA1* and *BRCA2* proteins are both involved in a form of DNA double strand break repair known as homologous recombination repair (HR). DNA double-strand breaks are repaired in an error-free manner by reference to the opposite double strand existing in the G2 phase of the cell cycle. *BRCA1/2* mutation carriers have one functional and one nonfunctional allele and can therefore carry out HR. However, the tumors they develop have lost the function of the second allele and are therefore HR deficient. PARP inhibitors prevent the repair of sporadically occurring single strand breaks and lead to an accumulation of single-strand breaks. When DNA replication takes place, these single-strand breaks are converted to double-strand breaks. In normal tissues, these are repaired by HR so PARP inhibitors are not particularly toxic. However, in the tumor arising in a *BRCA1/2* carrier HR is deficient, so the double strand breaks persist, leading to cell death. For a more detailed explanation, see reference 668.

Clinical Summary

PARP inhibitors have generally shown little or mild toxicity when given as single agents. The phase I study of rucaparib

showed no evidence of toxicity from the PARP inhibitor at doses that were capable of inducing significant inhibition of PARP in peripheral blood mononuclear cells and tumor biopsies (680). In a phase I trial of olaparib, doses were escalated to toxicity (681). Dose limiting toxicities occurred in 3 patients and were mood alteration, somnolence, and myelosuppression.

When PARP inhibitors have been used in combination with cytotoxic chemotherapy, there has been a marked potentiation of the myelosuppression induced by the chemotherapy; this is consistent in all the reported studies and exemplified by (682). Owing to this, at the time of writing, the clinical value of such combinations has not been established.

The most remarkable clinical results obtained to date results are those in patients with *BRCA1/2*-related cancers treated with olaparib. Phase II studies of olaparib have shown response rates of 41% in breast cancer (683) and 33% in ovarian cancer (684), both groups of patients having advanced, pretreated disease. High response rates have also been observed in relapsed serous ovarian cancer patients and in patients who are not carriers of a germline *BRCA* mutation (685). This is thought to be because the tumor has an acquired HR deficit, making it respond in the same way as one with an HR deficit resulting from a *BRCA1/2* mutation. The activity of PARP inhibitors in high-grade serous ovarian cancer has been further demonstrated by a randomized phase II maintenance study conducted in patients who received 2 or more platinum-based regimens and had a partial or complete response to their most recent platinum-based regimen. There was a significant improvement in progression-free survival from 4.8 to 8.4 months (hazard ratio = 0.35, $p < 0.001$), and the improvement was observed both in patients with and without *BRCA* mutations (686).

PARP inhibitors have many potential roles in gynecological cancers, including as single agents (as described above), to potentiate other drugs (especially platinum), and as potentiators of radiotherapy. These applications are currently an area of active clinical exploration.

Eribulin

Chemistry

Eribulin is a synthetic derivative of the natural product Halichondrin B, a product originally isolated from a marine sponge. It acts as a microtubule dynamics inhibitor. The chemical name for eribulin mesylate (the injectable form) is 11,15:18,21:24,28-Triepoxy-7,9-ethano-12,15-methano-9H,15H-furo[3,2-*i*]furo[2',3':5,6]pyrano[4,3-*b*][1,4]dioxacyclopentacosin-5(4H)-one, 2-[(2S)-3-amino-2-hydroxypropyl]hexacosahydro-3-methoxy-26-methyl-20,27-bis(methylene)-, (2R,3R,3aS,7R,8aS,9S,10aR,11S,12R,13aR,13bS,15S,18S,21S,24S,26R,28R,29aS)-, methanesulfonate (salt). It has a molecular weight of 826.0 (729.9 for free base). The empirical formula is $C_{40}H_{59}NO_{11} \cdot CH_4O_3S$.

Mechanism of Action

Eribulin binds to tubulin and sequesters it into nonproductive aggregates, thereby inhibiting mitosis and causing a G2/M cell cycle block.

Drug Disposition

Eribulin is administered intravenously. The majority of the dose is excreted unchanged in the feces, with only approximately 9% in the urine. There is little metabolism, with approximately 90% of the drug being excreted unchanged. The volume of distribution is approximately 40 L and the half-life about 40 hours.

Dosage

The recommended dose of eribulin for patients with normal hepatic function is 1.4 mg/m² administered intravenously over 2 to 5 minutes on days 1 and 8 of a 21-day cycle. Dose reductions to 0.7 mg/m² are recommended for patients with mild hepatic impairment and to 1.1 mg/m² for patients with moderate renal impairment.

Further dose reductions are recommended according to the level of myelosuppression encountered during treatment.

Side Effects and Toxicities

The dose-limiting toxicity of eribulin is myelosuppression. Peripheral neuropathy also occurs. In one study, grade 3 was seen in 8% (40/503) of patients and grade IV in 0.4% (2/503). This side effect is probably less frequent than with the taxanes (paclitaxel and docetaxel). QT prolongation has also been reported. Other adverse events that have been reported in greater than 10% of patients include asthenia, constipation, diarrhea, nausea, and vomiting.

Drug Interactions

As noted above there is little CYP mediated metabolism of eribulin and no significant drug interactions are expected [H71].

Clinical Summary

Eribulin is licensed for the third-line treatment of metastatic breast cancer. A randomized trial of eribulin versus single-agent therapy (chosen before randomization) showed an overall benefit of 2.6 months (10.6 ± 1.4 vs. 13.2 ± 1.1).

There are few data concerning its use in gynecological tumors. A phase II study in ovarian cancer enrolled 37 platinum-sensitive and 37 platinum-resistant patients and showed response rates of 5.5% and 19%, respectively [H72].

Ixabepilone

Chemistry

Ixabepilone is a semi-synthetic epothilone microtubule inhibitor. Epothilone is a natural product isolated from a myxobacterium, *Sorangium cellulosum*. Ixabepilone is modified by replacing the naturally occurring lactone in the macrocycle by a lactam, indented to reduce the rate of metabolism of the ring. The chemical name for ixabepilone is (1S,3S,7S,10R,11S,12S,16R)-7,11-dihydroxy-8,8,10,12,16-pentamethyl-3-[(1E)-1-methyl-2-(2-methyl-4-thiazolyl)ethenyl]-17-oxa-4-azabicyclo[14.1.0]heptadecane-5,9-dione, and it has a molecular weight of 506.7.

Mechanism of Action

Ixabepilone stabilizes $\alpha\beta$ -II and $\alpha\beta$ -III microtubules, leading to the death of proliferating cells via a block in the mitotic phase of the cell cycle. Ixabepilone has a low affinity for the efflux pump proteins MRP1 and P-glycoprotein, which are known causes of resistance to taxanes. It is also active in human tumor xenografts that over-express β III tubulin isoforms or have tubulin mutations conferring resistance to taxanes. Further, it is active in human tumor xenograft models that are resistant to other commonly used anticancer drugs such as anthracyclines and vinca alkaloids [H73].

Drug Disposition

Following IV injection of ixabepilone, the mean volume of distribution has been reported as in excess of 1,000 L, indicating a very high tissue distribution [H73]. The clearance has been

reported as 475 ± 247 mL/min/m², the half-life at 14 hours [H74]. Plasma protein binding was in the region of 67% to 77% [H73]. Ixabepilone is eliminated primarily as the metabolized drug in the feces. Approximately 86% of an administered dose was eliminated in 7 days, with 65% of the dose in the feces and 21% of the dose in the urine. Unchanged ixabepilone was 1.6% and 5.6% of the recovered dose, respectively. Ixabepilone is extensively metabolized in the liver, and studies with human liver microsomes suggest that CYP3A4 is the primary route [H73].

Dosage

The recommended dosage of ixabepilone is 40 mg/m² administered intravenously over 3 hours every 3 weeks. Dose adjustments are recommended for hematological and neurological toxicities. One of the license indications for ixabepilone is for use in combination with capecitabine (see below). Ixabepilone with capecitabine is contraindicated in patients with AST or ALT $>2.5 \times$ ULN or bilirubin $>1 \times$ ULN due to increased risk of toxicity and neutropenia-related death [H73].

In order to minimize the chance of hypersensitivity reactions, it is recommended that all patients receive premedication with a H1 and H2 inhibitor. Patients who experience a hypersensitivity reaction should receive treatment with corticosteroids.

Side Effects and Toxicities

Dose-dependent myelosuppression can occur, with grade 4 neutropenia reported in 36% of patients. Myelosuppression is more severe in patients with hepatic impairment. Peripheral neuropathy

is common and has been reported in approximately 65% of patients treated, with 14% to 21% being grade 3/4.

Drug Interactions

Drug interactions are to be expected with other drugs that are metabolized by (e.g., ketoconazole) or induce (e.g., rifampin) CYP3A4. These 2 drugs have been shown to increase and decrease the exposure to ixabepilone by +79% and -43%, respectively. It is recommended that strong inhibitors or inducers of CYP3A4 are avoided where possible, and dose modifications are considered when any strong or weak inducer of inhibitor is used [H73].

Clinical Summary

Ixabepilone is licensed for use as monotherapy for the treatment of metastatic or locally advanced breast cancer after the failure of an anthracycline, a taxane and capecitabine, or in combination with capecitabine after the failure of an anthracycline and a taxane.

In a study of 752 patients randomized to capecitabine or capecitabine + ixabepilone, the progression-free survival increased from 4.1 months (3.1 to 4.3) to 5.7 months (4.8 to 6.7), $p < 0.0001$ [H73].

A phase II study of 51 patients with taxane and platinum-resistant ovarian cancer had an overall response rate of 14.3%, with 3 complete and 4 partial responses [H75].

A phase II trial in 52 patients with pretreated endometrial cancer documented one partial response [H76].

Immunotherapy of Gynecologic Malignancies

PAUL J. SABBATINI ■ KUNLE ODUNSI ■ JACOBUS PFISTERER ■
GEORGE COUKOS

The natural clinical history of ovarian cancer makes it particularly suited for the evaluation of immune-based strategies. Although the majority of patients are diagnosed with advanced disease, 70% are in a complete clinical remission following initial cytoreductive surgery and platinum and taxane-based primary chemotherapy (1). However, only 30% of optimally debulked stage III patients will remain disease-free with a median progression-free interval of approximately 24 months (2). Despite the high relapse rate, many patients return to a complete or partial clinical remission following additional chemotherapy, but ever-shortening intervals of response are seen (3). Despite this chronic course of relapse and response, the median survival of optimally debulked patients exceeded 60 months in a study evaluating intraperitoneal (IP) therapy as part of primary treatment (4). Neither higher doses nor protracted schedules, nor non-cross-resistant consolidation chemotherapy has provided additional benefit. Ovarian cancer patients with minimal disease burdens are therefore appropriate candidates for the evaluation of immune-based strategies, which typically have excellent side-effect profiles.

With regard to other gynecologic malignancies, the majority of immune strategies being evaluated in patients with cervical cancer target human papillomavirus, and this subject is covered separately in the appropriate chapter (5). The evaluation of immune-based approaches for the treatment of endometrial cancer is limited but interest is growing (6). Targets such as human trophoblast cell surface marker (TROP-2), Wilms Tumor Gene (WT-1), and a variety of cancer testis antigens have been shown to be expressed in endometrial cancers which has prompted early stage trials with dendritic cell vaccines and adoptive cellular therapy as two examples (7,8). The bulk of the clinical information available to date with regards to immunotherapy when one excludes cervical carcinoma, however, remains in patients with ovarian cancer.

CANCER IMMUNOLOGY: OVERVIEW

The immune system evolved to fight foreign invaders such as bacteria, viruses, and parasites. However, strong evidence suggests that it also plays a crucial role in controlling or rejecting incipient cancers. William B. Coley first observed regression in patients with sarcoma contracting “accidental erysipelas” as early as 1893 (9). Since patients with competent immune systems still develop cancers, and spontaneous remission of tumors is rare, enthusiasm for the effectiveness of immune system control has waxed and waned over the decades. The fact that animal models with a variety of deficiencies in immunologic components consistently develop carcinoma has allowed the concept of immunosurveillance to be sustained and developed (10,11).

Observations in patients with ovarian cancer strongly support a role for immune system involvement in patient outcome. For example, the 5-year overall survival in epithelial ovarian cancer has been correlated to the presence or absence of tumor infiltrating lymphocytes (TIL) (38% vs. 4.5%, $p < 0.001$) (12). A second study also showed improved survival in patients with increased frequencies of intraepithelial CD8+ TIL (55 months vs. 26 months; HR = 0.33; 95% CI, 0.18–0.60; $p = 0.0003$) (13). In contrast, patients with increased numbers of immune suppressive CD4+CD25HI regulatory T-cells (Tregs) have reduced survival (14). The process is made more complex when we recognize that not only can the immune system protect the host against tumor development, but it is thought to select cancer cells of lower immunogenicity which can escape early immunity due to changes in gene expression. This actually leads to an outgrowth of tumors with the capacity to escape recognition and this process has been termed immunoediting (15). The immunoediting or “immune sculpting” process, therefore, is responsible for shaping the immunogenicity of the tumors that will eventually form. Considering the effectors of the immune system in the context of both of these processes is important in order to develop immune directed therapies with the greatest chance of success (16,17).

The mechanism by which tumors escape from immune surveillance is complex. An alteration in the function of almost every process discussed herein to facilitate immune activation has been postulated to participate in the ways tumors can evade immune detection. In some cases, antigen presentation is down regulated, or gene deletions or rearrangements may cause reduced expression of the MHC-I complex thus preventing T-lymphocyte activation (18,19). Tumors can also secrete proteins that inhibit T-cell effector action or that promote the development of regulatory T-cells that suppress immune function (20). A recent observation showed that certain melanomas can actually remodel their stromal microenvironment so it resembles lymphoid tissue which recruits regulatory cells to promote tolerance and allow tumor progression (21). Other mechanisms include the downregulation of intracellular adhesion molecules (22), changes in molecules responsible for apoptosis signaling (23), or the development of peripheral tolerance (24). Based on the increasing number of interacting mechanisms with putative activity that allow immune escape, approaches directed against multiple mechanisms will likely be needed in order to eradicate immune tolerant tumor cells (25).

Innate Immunity

The immune system is broadly divided into 2 arms, innate and active immunity, but there are multiple examples of cross communication between them. Recent data, for example, show that neutrophil survival is influenced by T cell responses (26).

Innate immunity is present at birth and does not require adaptation to react against microorganisms or tumors. It includes physical barriers (mucous membranes, skin), chemical components (complement, hydrolytic enzymes), and multiple other cellular components. For example, natural killer cells are lymphocytes that are programmed to recognize and destroy tissues that have been altered or stressed, e.g., by viruses or by malignant transformation (27). They do not have antigen specific receptors but instead have inhibiting receptors that can recognize MHC class I molecules on normal cells, which prevents their activation (28). MHC I expression is aberrant or absent on many virus and tumor infected cells (29). Another component includes macrophages, which play many roles in immunity and inflammation, including production of a multitude of soluble secreted proinflammatory proteins, which are growth factors for other cells of the immune system, for neovasculature, and for cancer cells. These growth factors include *cytokines* and *chemokines*, and they support the growth, movement, and survival of immune and inflammatory cells. Macrophages play important roles in tissue remodeling during wound healing, mediating inflammatory responses, sampling molecules from the environment through internalization, and presenting antigens to stimulate T cells. Macrophages can also play a counterproductive role through production of molecules that promote tumor growth and angiogenesis (e.g., vascular endothelial growth factor [VEGF] and basic fibroblast growth factor [FGF]) (30). Macrophages can also inhibit immune responses through production of cytokines and other molecules that down-regulate immunity, such as prostaglandins E₂, arginase I, and transforming growth factor- β . Thus, the role of macrophages in tumors is complex: they provide an additional means of communication between traditionally defined innate and acquired immunity effectors (31). Dendritic cells have some properties that are similar to macrophages, including production of cytokines and sampling of molecules from the environment. Most importantly, dendritic cells are one of the key links between the innate immune system and the adaptive or acquired immune system through presentation of antigens (professional antigen-presenting cells) to initiate T-cell activation.

Adaptive Immunity

Adaptive immunity is characterized by adaptation to antigens, for example, antigens of infectious pathogens (or potentially by cancer). This arm of the immune system is not mature or activated at birth, but rather adapts through maturation in response to antigens of pathogens. It is characterized by receptors encoded by the immunoglobulin (Ig) gene family. These receptors have the capacity to rearrange, creating enormous diversity (>10 different receptors) (11–12). This provides a system to generate enormous specificity that recognizes and responds to a wide range of antigens that have not previously been encountered.

The two major cell types of acquired immunity are *T lymphocytes* (T cells) and *B lymphocytes* (B cells). T cells have the capacity to recognize antigens sequestered in different compartments within cells, for instance, antigens generated in the cytoplasm or nucleus by viral infections (32). T cells recognize antigens as short peptides, 8 to 16 amino acids in length. These peptides must be complexed with and presented by specialized antigen-presenting molecules, the major histocompatibility complex (MHC) molecules, to T-cell receptors. In humans, MHC molecules are the human leukocyte antigens (HLAs) expressed on virtually every cell in the body. On the other hand, B cells produce secreted *antibodies* that can recognize soluble and cell surface molecules. Both T cells and B cells initially develop with a limited range of receptors for immune recognition. However, in response to antigen (e.g., from a virus or cancer cell) presented by a professional antigen-presenting cell, T cells or B cells

that have receptors with the best “fit” to the antigen itself (for B cells) or antigen/MHC complex (for T cells) are stimulated to proliferate and this subpopulation is quickly expanded (33).

Humoral Immunity

B cells recognize antigens usually in their natural configuration (32). An individual host has a repertoire of B cells that are capable of generating antibodies against the full range of pathogens encountered in the environment. To do this, the total population of B lymphocytes expresses a diverse repertoire of immunoglobulins. Each B cell expresses immunoglobulin against a single antigenic determinant, with the immunoglobulin expressed at the cell surface of the B cell where it acts as a specific receptor to transduce signals in response to that antigen (34). Once activated, the B cell is to create an individual monoclonal antibody (mAb). The diversity of specificities in different B cells is generated by rearrangements of the immunoglobulin genes, and new antibody specificities continue to be generated in response to new antigens (35). During development, B cells with high avidity immunoglobulins against ubiquitous self-antigens are eliminated. This elimination of B cells reactive with autoantigens is not absolute, however, as a broad array of antibodies against autoantigens is found in the blood of humans. Peripheral blood B cells consist of naïve and relatively short-lived B cells, long-lived memory B cells resulting from maturation in response to antigenic stimulation, and a small population of B cells expressing germ-line immunoglobulins that have not undergone rearrangement (which are found in the CD5+ B-cell population) (13).

B cells are mobile and after development in the bone marrow they migrate through the peripheral blood to B-cell-rich areas in lymphoid organs, e.g., the follicles of lymph nodes, spleen, and gastrointestinal tract. Many B cells continue recirculating in the blood. If cognate antigen is encountered in lymphoid organs, the B lymphocyte migrates to the T-cell-rich areas where appropriate T-cell help can be provided to promote increased antibody diversity and increased affinity through immunoglobulin gene rearrangements (36). This T-cell help does not have to be induced by the same antigen. Chemical conjugation of the antibody-recognized antigen to highly immunogenic bacterial or xenogeneic proteins or, alternatively, expression of the antigen in bacterial or viral vectors, is widely used approaches to ensure adequate T-cell help in vaccines. The result of T-cell help is generation of plasma cells, the most mature form of B cell with the highest capacity for antibody production. In addition, T-cell help promotes formation of germinal centers in lymphoid organs where hypermutation in immunoglobulin genes and class and subclass switching occur to generate antibodies with higher affinities for antigen. Class switching refers to changes in antibody class during an immune response, with the IgM class of antibodies appearing first, generally followed by antibodies of the IgG class (different subclasses of IgG antibodies have different blood half-lives and different capacities for effector functions, such as fixation of complement or binding to Fc receptors). The consequence is plasma cells secreting increasingly higher affinity IgG antibodies as the immune response matures over time (37). In addition, some B cells that generally recognize nonprotein antigens, such as carbohydrate or glycolipid antigens, can be stimulated to proliferate in the absence of T-cell help. The immunoglobulin variable region (called the Fv region) determines antibody specificity and is located in the Fab domain of immunoglobulins. This region mediates effective binding to antigens. However, the constant region (Fc), where antibody class and subclass are determined, is equally critical. Binding of antibody to antigen results in a conformational change in the Fc portion, leading to activation of several effector mechanisms, including complement activation (discussed below). IgM antibodies are synthesized early in the response. If T-cell help is

available, antibody responses mature through immunoglobulin gene rearrangements into the higher affinity IgG classes. These are capable of improved binding to antigen as well as receptors on the bone marrow-derived cells for the Fc domain, expanding potential effector functions. The responses to most nonprotein antigens are IgM class and generally do not mature to IgG responses. The IgM pentamer structure is specialized to increase avidity of binding to multimeric antigens and to efficiently activate effector functions such as complement (38). Activation of complement, which includes blood components with different enzymatic properties, results in opsonization (coating of pathogens by complement components), recognition by complement receptors on macrophages, monocytes, neutrophils, and dendritic cells, with subsequent activation of these cells leading to phagocytosis and/or killing. In addition, complement can form a membrane attack complex, which creates holes in membranes of target pathogens and cancer cells, producing complement-dependent cytotoxicity (CDC) (39,40). IgG antibodies are synthesized following immunoglobulin gene rearrangements, with switches in Fc domains, as the B cell matures in response to T-cell help. IgG antibodies usually have higher affinity, and can be found in the extracellular space as well as in the blood. IgG1 and IgG3 antibodies in humans are especially effective at activating complement and also at sensitization of pathogens for killing by NK cells, macrophages, and other cells with complement receptors and immunoglobulin Fc receptors (41).

Opsonization for ingestion and destruction by phagocytes can occur through complement activation, but also occurs directly as a consequence of engagement of Fc receptors on phagocytic cells. Antibodies complexed to antigen bind to Fc receptors, which can lead to activation signals through activating Fc receptors (e.g., FcRIII), but activation can be countered by IgG binding to the inhibitory Fc receptor, FcRIIB. Fc receptors, which are bound effectively by IgG1 and IgG3 subclasses of human antibodies, are expressed on monocytes, macrophages, NK cells, neutrophils, mast cells, and other cells. Cross-linking of Fc receptors leads to activation of the cells, in some cases leading to antibody-dependent cell-mediated cytotoxicity (ADCC) of tumor cells through production of cytotoxic molecules, such as perforin and granzyme by NK cells and reactive molecular species by macrophages (42–44). Monoclonal antibodies are commonly used for cancer therapy. Antitumor effects can be mediated in part by antibody binding to critical molecules on the surface of tumor cells, for example by inhibiting tumor cell attachment or growth receptors. However, generally interactions of antibody with cell antigen are not very effective unless Fc receptor-mediated effector mechanisms are also activated.

Cellular Immunity

T lymphocytes recognize processed (digested) molecules that complex with MHC molecules within antigen-presenting cells. The antigen/MHC molecules are then trafficked to the cell surface for recognition by T-cell receptors, which are encoded by genes of the immunoglobulin family. Similar to generation of antibodies, great diversity of T-cell receptors is generated by rearrangements of these immunoglobulin family genes. Each monoclonal T-cell receptor must bind to its cognate antigen/MHC complex (CD4 cells bind to MHC class II molecules, and CD8 cells bind to MHC class I molecules) presented on the surface of antigen-presenting cells (45,46). Signaling from the T-cell receptor following engagement of antigen/MHC complex is insufficient to activate the T cell. Additional signals are required (co-stimulatory signals or “signal 2”). The most important co-stimulatory signal in T cells comes from the T-cell surface molecule CD28, which engages B7 molecules (CD80 and CD86) on antigen-presenting cells (47–49). Engagement of T-cell receptor by antigen/MHC in conjunction with CD28 engagement

of B7 is sufficient to activate naïve T cells. Within several days following T-cell activation, a second molecule, CTLA-4, appears on the T-cell surface to provide a brake to the T-cell response. CTLA-4 also binds B7 molecules, but with much higher affinity, therefore displacing CD28 activation signals. CTLA-4 signaling leads to down-regulation of the T-cell response. The manipulation of CTLA-4 activity has recently been shown to have therapeutic efficacy with recent data showing tumor responses in patients with melanoma (50,51). A variety of other co-stimulatory molecules are up-regulated on the surface of activated T cells, including OX40 and 4-1BB, which promote survival of T cells and help generate long-lived T-cell memory responses (52,53). Once T cells are activated by professional antigen-presenting cells (primarily dendritic cells), they gain a variety of effector functions, including the production of cytokines and cytotoxic molecules, which lead to death of target cells.

Antigen-Presenting Cells

Dendritic cells are the prototype professional antigen-presenting cells and are the critical link between innate immunity and acquired immunity. These are phagocytic cells that sit on epidermal surfaces, including skin and mucosal membranes, constantly sampling their environment to search for infectious organisms. Although dendritic cells continuously ingest molecules from their environment, uptake of antigen is insufficient to activate dendritic cells. Rather, dendritic cells have a set of receptors, most notably the toll-like receptors (TLRs), which can recognize lipid-containing molecules and CpG-rich DNA and poly-U RNA sequences produced specifically by microbial organisms. Engagement of TLR signals for activation of the dendritic cell, with increased expression of MHC and B7 molecules, and movement of cells with captured antigen to draining lymph nodes. It is in draining lymph nodes that dendritic cells activate appropriate T cells that recognize that particular antigen presented by MHC molecules. Subsequently, activated T cells can then travel from the draining lymph node to distant sites of infection or tumor to carry out the effector functions. One of the central problems for cancer immunology is that dendritic cells may ingest and process cancer antigens, but without activation through TLRs or other receptors, the dendritic cells remain incapable of activating T cells (because of insufficient expression of co-stimulatory molecules, such as B7) and do not move to draining lymph nodes. In fact, insufficiently activated dendritic cells presenting antigens can induce energy, a form of immune tolerance where T cells become paralyzed and incapable of responding to cognate antigens. This is one of the mechanisms used to maintain immune tolerance to self to prevent autoimmunity, but also presents a major hurdle for cancer immunity. Cancer cells do not have any readily apparent mechanism to activate dendritic cells, although several self molecules, including heat shock protein, hyaluronate, and uric acid crystals have been suggested to cause activation.

Helper and Regulatory T Cells

Several types of T cells are activated by dendritic cells, and which type is influenced by whether antigens are presented by MHC class I or MHC class II molecules on antigen-presenting cells. MHC class I molecules complexed with antigen stimulate CD8+ T cells that are cytotoxic and kill target cells (infected cells or tumor cells). Antigens presented by class II MHC molecules stimulate CD4+ helper T cells. Helper T cells produce chemokines and cytokines to help recruit and orchestrate other components of the immune system. Helper T cells come in several types and different cytokines in the milieu determine what type of T cell is generated. Each type of helper T cell mediates

different types of immune responses with different characteristics. Th1 T cells produce interferon (IFN)- γ to activate cytotoxic T cells and macrophages for *cellular immune responses*. On the other hand, Th2 helper T cells produce interleukin (IL)-4 and other cytokines that favor antibody responses, or *humoral immunity*. The newly discovered Th17 CD4⁺ T cell produces IL-17 to mediate inflammatory autoimmune diseases, such as arthritis, colitis, and encephalitis, and may play a role in cancer pathogenesis, either by promoting cancer progression or by destroying tumors. Another type of CD4⁺ T cell restricted by MHC II presentation negatively regulates immune responses. These are regulatory T cells, or Tregs. Tregs recognize self antigens, are dependent on IL-2, and produce inhibitory molecules such as IL-10 and transforming growth factor- β . Th1 cellular immunity may be particularly effective at attacking tumors in tissues, while humoral immunity may have an advantage in controlling circulating metastatic tumor cells. Infiltration of ovarian cancers and other cancers by Treg cells is associated with a poorer prognosis (50,54).

CANCER IMMUNITY AND IMMUNOTHERAPY

Careful studies over the past 3 decades have shown that the immune system can recognize and destroy cancers, usually involving interactions between multiple arms of the immune system. For instance, simple recognition by T cells, antibodies, or NK cells is usually not sufficient to reject cancers. Cytotoxic T cells and NK cells produce soluble and cell surface molecules that induce death of target tumor cells. Helper T cells can produce cytokines and chemokines that not only recruit cytotoxic T cells or B cells to make antibodies, but also inflammatory cells which mediate tissue destruction. Antibodies can activate NK cells, macrophages, or other cells that have receptors for the antibodies' Fc domain, leading to activation of the recruited cells, a mechanism implicated in the antitumor effects of monoclonal antibody therapies. Antibodies can also activate complement proteins in the blood that can directly kill tumor cells and activate inflammatory cells at the tumor site.

The abundant evidence that the immune system can recognize antigens on tumor cells and that immunity is sufficient to destroy tumors, provides the impetus to continue and develop strategies for *immunotherapy*. These approaches can be broadly divided into three groups. First, *immune modulation* uses more broad approaches to treat cancer. Traditional examples include cytokines such as IL-2, IL-12, or interferons, and more recently more targeted approaches such as those interfering with CTLA-4 or PD-1 (51). Secondly, *passive therapy* refers to the transfer of specific components from the acquired immune system to the host with cancer. The best examples are monoclonal antibodies directed against antigens expressed on the surface of cancer cells such as rituximab against the CD20 antigen, or trastuzumab (Herceptin) directed towards the HER 2 receptor in breast cancer. It should be noted that although the antitumor effects of trastuzumab in part probably involve inhibition of signaling by the HER2 tyrosine kinase oncogene, evidence strongly supports a major role for immune activation of Fc receptor-positive cells by both rituximab and trastuzumab (55). Another example of passive immunotherapy is adoptive cellular therapy, where cells from the blood or bone marrow donor are purified, cultured, and/or manipulated outside the body and reinfused into the same patient (autologous) or a different patient (allogeneic). Cellular therapy has particularly focused on T cells and more recently on NK cells. Finally, *active immunization* refers to vaccines that trigger the patient to make an immune response. Both passive and active immunotherapy must be directed against specific antigens on cancer cells, and the notion of an

Table 15.1 Antigenes for Immunotherapy

Antigen Category	Representative Examples
Differentiation antigens	Tyrosinase (62), Melan-Mart-1(302), gp-100 (303)
Mutational antigens	CD4 (63), β -catenin (304), caspase (305)
Amplification antigens	HER2/neu (64), P53 (306)
Splice variant antigens	NY-CO-37/PDZ 45 (65), ING1 (307)
Glycolipid antigens	MUC1 (66)
Viral antigens	HPV (67)
Cancer testis antigens	MAGE (68), NY-ESO-1 (308), LAGE-1 (309)

integrated immune response with effectors to include antibodies and T cells as well as some component of immunomodulation is increasingly becoming the goal of immunotherapeutic strategies (56).

With regards to potential targets, ongoing advances utilizing newer technologies including serological analysis of recombinant cDNA expression libraries (SEREX) (57,58), robust applications of bioinformatics (59) and seromic profiling techniques (60) have allowed the further characterization of tumor associated antigens in multiple tumor types. There are over 2000 candidate tumor associated antigens and they are generally classified as follows: (61) (a) differentiation antigens (62), (b) mutational antigens (63) (that are altered forms of proteins), (c) amplification antigens (64), (d) splice variant antigens (65), (e) glycolipid antigens (66), (f) viral antigens (67), and (g) cancer-testis (CT) antigens (68). Representative examples of each group are seen in Table 15.1.

In addition to selecting the appropriate targets, it is necessary to select the strategy to be used for immunotherapy. Multiple approaches have been considered from giving the effector cells directly to include antigens of a variety of types given alone or with adjuvants, modified or unmodified tumor cell lysates can be administered (autologous or allogeneic), dendritic cells can be primed with a variety of agents, tumor hybrids with antigen-presenting cells can be made, or DNA alone or in a recombinant fashion can be administered. A sample of cancer vaccine strategies are listed in Table 15.2.

Table 15.2 Examples of Vaccine Approaches

- I. Antigens alone with or without adjuvants
 - Peptides
 - Protein
 - Gangliosides
 - Immunoglobulin idiotypes
- II. Dendritic cells
 - Peptides, immunoglobulin idiomorph
 - Tumor lysates
 - DNA or RNA
 - Protein
- III. Tumor cells unmodified or modified
 - Autologous
 - Allogeneic
 - Mixed autologous-allogeneic
- IV. Tumor-APCs hybrid
- V. DNA alone (naked DNA), recombinant viruses (adenovirus, vaccinia, and others)

A critical component of any immune approach is a consideration of immune escape. Tumors escape destruction by the immune system via a variety of active, regulatory mechanisms. These include downregulation of MHC and tumor antigen loss (69), stimulation of the inhibitory receptors on T-cells such as CTLA-4 (70), PD-1 and LAG-3 (71), tumor overproduction of indoleamine 2,3-dioxygenase (IDO) (72), induction of increased tumor infiltration by regulatory CD4⁺CD25⁺ T cells (Tregs) (73) and also certain types of natural killer T (NKT) cells that inhibit tumor immune destruction (74). Overcoming these mechanisms is the goal of immunomodulation.

IMMUNOMODULATION

Multiple potential difficulties remain in developing new immunotherapy approaches, including insufficient activation of dendritic cells by cancer cells, inhibition of responses by Treg cells, and both intrinsic and extrinsic mechanisms that down-regulate T-cell responses, e.g., signaling through CTLA-4. These checkpoints all participate to dampen immune responses against cancer. Modulating immune check points by activation of effector cells, depletion of Tregs or activation of professional APCs could substantially improve the therapeutic efficacy of vaccines or adoptively transferred T cells. The development of functional antibodies is now enabling effective immunomodulation as shown in Figure 15.1. Passive therapy with monoclonal antibodies or with adoptive cellular treatments may also be able to bypass some of these checkpoints.

Dendritic Cell Activation

The main mechanism of immune stimulation by CD 40 ligands is activation of DCs resulting in increased survival, upregulation of costimulatory molecules, and secretion of critical cytokines to T cell priming such as IL-12. This promotes antigen presentation, priming and cross priming of CD4⁺ and CD8⁺ effector T cells (75). However, agonistic anti-CD40 antibody

is best used in combination with vaccines or Toll-like receptor agonists (75,76), because alone it can accelerate the deletion of tumor-specific cytotoxic lymphocytes (77). Additional value of CD40 ligation is provided by the fact that ovarian cancers, like many tumors, express the CD40 receptor (78–81) and respond to CD40 agonists with apoptosis and growth inhibition *in vitro* and *in vivo* (80,82,83).

Effector T-cell Activation

T-cell activation is triggered through the T-cell receptor by recognition of the cognate antigen complexed with MHC. This activation is regulated by complex signals downstream of CD28 family immune receptors, which includes costimulatory (CD28 and ICOS) and inhibitory receptors (CTLA-4, PD-1 and BTLA). PD-1 and CTLA-4 are induced on T cells following a TCR signal, and result in cell cycle arrest and termination of T-cell activation. The use of blocking CTLA-4 or PD-1 mAbs can sustain the activation and proliferation of tumor-specific T cells, preventing anergy or exhaustion and thereby allowing the development of an effective tumor-specific immune response.

CTLA-4 Blockade

CTLA-4 is the best characterized among the inhibitory B7 receptors. As with CD28, CTLA-4 also binds CD80 and 86 expressed by APCs, but provides inhibitory signals to the T cell, serving as a negative feedback loop. In animal models, CTLA-4 proved critical in the normal functioning immune system. CTLA-4 knockout mice develop uncontrolled lymphoproliferation with early lethality. Furthermore, administration of CTLA-4 blockade significantly enhanced antitumor immunity in a variety of mouse models and with various therapeutic combinations including vaccine, TLR agonist, chemotherapy and radiation therapy. The mechanism by which CTLA-4 blockade induces tumor regression is not fully understood. Although Treg constitutively express CTLA-4, CTLA-4 blockade had no effect on the number or function of Treg in cancer patients. It seems that CTLA-4 blockade activates directly CD4⁺ and CD8⁺ T effector cells

FIGURE 15.1 The modulation of immune checkpoints.

by removing an inhibitory checkpoint on proliferation and function (84). The combination of direct enhancement of T cell function and inhibition of Treg activity is essential for mediating the full therapeutic effects of anti-CTLA-4 antibodies during cancer immunotherapy (85).

Based on these data, several clinical studies have been undertaken to assess the efficacy of a CTLA-4 antagonist antibodies in the setting of human cancer. The majority of clinical data to date have emerged from studies in patients with melanoma (reviewed in (86)). Phase II studies with ipilimumab monotherapy showed objective responses at a dose of 3 to 9 mg/kg every 3 weeks, with 10 mg/kg showing the best risk-benefit profile. Ipilimumab (3 mg/kg every 4 weeks x 4) administered in combination with *chemotherapy* (dacarbazine) resulted in enhanced objective response rates without added toxicity. Ipilimumab has also been combined successfully with IL-2 (720,000 U/kg every 8 hours x 15 (OR rate of 22% - 3 CRs) or melanoma vaccine (OR rate of 13% - 2 complete responses). In addition, tremelimumab has also produced OR and CRs in melanoma patients. To date, CTLA-4 antibody has not shown superiority over standard chemotherapy trial in treatment-naïve melanoma patients in a phase III randomized clinical, which was discontinued after interim analysis. In melanoma patients, the most common grade 3 to 4 adverse events were colitis/enterocolitis (increased frequency of diarrhea/stools), dermatitis, and hypophysitis.

Eleven patients with ovarian carcinoma, previously vaccinated with GM-CSF modified, irradiated autologous tumor cells (GVAX), received ipilimumab (1 month to 3 years following GVAX). Significant antitumor effects were observed in a minority of the patients. One patient achieved a dramatic fall in CA-125 levels several months after an initial dose of ipilimumab; although the response was not maintained, a second infusion resulted in a more rapid decline in CA-125 values. Nine additional infusions of the anti-CTLA-4 antibody spaced at 3- to 5-month intervals over nearly 4 years have maintained profound disease control, with grade 1 rash as the only adverse event. An objective radiographic response was noted in parallel with the reduction in CA-125. Moreover, this patient's course was initially characterized by a remarkable periodicity to the rise and fall of CA-125 levels, but this gradually dampened as a function of time and/or prolonged therapy, demonstrating a lack of acquired resistance to ipilimumab commonly observed with cytotoxic chemotherapy (87). In contrast to the melanoma cohort, a single dose of 3 mg/kg Ipilimumab triggered 2 cases of grade 3 gastrointestinal inflammation among the 9 ovarian carcinoma patients, consistent of significant diarrhea. Endoscopic biopsies revealed mucosal damage associated with abundant granulocytes, macrophages, CD4+ and CD8+ T cells, and FoxP3+ Treg. The remaining seven patients showed only minor inflammatory toxicities including papular rash, or urticarial-like reactions at sites of prior vaccination (87). Tumor regression in these patients correlated with the CD8+/Treg ratio, suggesting that other forms of therapy that target Treg depletion may provide a highly effective form of treatment when combined with the tumor vaccine and CTLA-4 antibody arsenal (87).

PD-1 Blockade

Programmed death receptor-1 is a negative regulator of cell activation, primarily expressed on both B and T lymphocytes, which binds PD-L1 and PD-L2 ligands. PD-L2 is restricted to professional antigen-presenting cells, while PD-L1 is expressed on many tissues, and plays a pivotal role in maintaining peripheral tolerance. Importantly, cancer cells have adopted expression of PD-L1 into their immunosuppressive arsenal (88) and a variety of epithelial cancers express PD-L1 (89–91). It has also recently been shown that ovarian carcinoma cells as well as

tumor-infiltrating tolerogenic DCs and myeloid derived suppressor cells express PD-L1 (92,93). Furthermore, expression levels correlate with disease course. Although PD-1 signaling can occur at very low levels of receptor expression, elevated levels of PD-1 have recently been attributed functional significance. During conditions of chronic antigen persistence (such as in chronic viral infections), antigen specific effector T cells expressing high levels of PD-1 were demonstrated to be functionally exhausted, i.e., unable to proliferate, secrete IL-2, or kill target cells (94). It has been shown recently that tumor infiltrating lymphocytes in metastatic melanoma and other tumors expresses higher levels of PD-1 than CD4+ and CD8+ cells in the peripheral blood of healthy patients and exhibit phenotypic and functional characteristics of exhausted T cells with impaired effector function. These findings suggest that the tumor microenvironment can lead to up-regulation of PD-1 on tumor-reactive T cells and contribute to impaired antitumor immune responses (95). Indeed, constitutive or inducible expression of PD-L1 by tumors conferred resistance to immunotherapy in mice related to failure of antigen-specific CD8+ CTLs to destroy tumor cells but without impairment of CTL function (96).

Following evidence that PD-1 blockade through gene therapy approaches in the tumor microenvironment activates antitumor immunity (97), antibodies blocking PD-L1 or PD-1 were found to profoundly enhance the efficacy of immune therapy (96,98). Anti-PD-1 antibody has been combined with cell-based vaccines and demonstrated increased infiltration, potency and duration of activity of CD8 T cells in the tumor microenvironment in the setting of B16 melanoma and CT26 colon carcinoma in mice.

Despite their similarities, the regulatory roles of CTLA-4 and PD-1 may differ substantially in cancer patients. First, Even though PD-1 and CTLA-4 ligation efficiently block T-cell responses, the homeostatic function of the 2 inhibitory receptors differs. For example, CTLA-4 ligation does not inhibit PI3-kinase signaling, while PD-1 engagement blocks the induction of PI3K activity. PD-1-mediated signaling blocks T-cell activation more effectively than CTLA-4-mediated signaling. In addition, PD-1 signaling may be related to T-cell apoptosis. Second, whereas the ligands for CTLA-4, CD80 and CD86, are primarily expressed by mature antigen-presenting cells, PD-L1 (on tumor cells or myeloid cells) and PD-1 (on effector T cells) are significantly upregulated in the tumor microenvironment. Thus, the effects of PD-1 blockade may be more pronounced in the tumor than in periphery. A phase I study using PD-1 blocking antibody showed the antibody to be safe and well tolerated in patients with hematologic malignancies. No single maximum tolerated dose was defined in this study. Clinical benefit was observed in 33% of the patients with one complete remission (99).

T Regulatory Cell Depletion

CD4+ CD25+ Foxp3+ T regulatory cells are responsible for maintaining peripheral tolerance by inhibiting T-cell activity. A number of Treg-depleting strategies have been investigated (100–104). An example is the use of low dose oral or intravenous cyclophosphamide (105,106). Other strategies for Treg depletion are through targeting the IL-2 receptor alpha chain, also known as CD25. In mouse models, the use of anti-CD25 monoclonal antibody before vaccination led to complete tumor rejection and establishment of long-lasting tumor immunity with no autoimmune complications (107,108). Administration of anti-CD25 antibody linked to a potent pro-inflammatory toxin showed significant but transient reduction in CD4+ CD25+ Treg cells in patients with metastatic melanoma (109). Another clinical approach of targeting CD25 is through Denileukin diftotox, a fusion protein of IL-2 and diphtheria toxin that targets

CD25-expressing cells used in patients with melanoma, ovarian cancer and renal-cell carcinoma (110–113). Although effective in short-term infusions, these conjugates are quite immunogenic and induce neutralizing antibodies, which hamper their long-term application.

Another agent is Daclizumab, which is an FDA-approved humanized IgG1-kappa mAb that binds specifically to CD25 (114). It has been used in autoimmune disorders (115,116), acute graft-versus-host disease (117), and in cancer patients with CD25⁺ T-cell malignancies (118). The advantage of Daclizumab is that it is well tolerated, and has a half-life of 20 days (119). In a recent study, Daclizumab was used in a single dose of 1 mg/m² prior to hTERT peptide vaccine for metastatic breast cancer. Total CD4⁺CD25⁺ and CD4⁺CD25⁺FoxP3⁺ cells remained suppressed for several weeks after a single infusion.

Cytokines

Cytokines play important roles in immune modulation. Many cytokines, including IL-2, IL-3, IL-4, IL-6, IL-10, IL-12, tumor necrosis factor- α (TNF- α), macrophage colony-stimulating factor, and IFNs, have been studied for their roles in tumor treatment. Some cytokines (IL-2 and IFN- α) have been approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of melanoma and renal-cell carcinoma though enthusiasm for use has waned given the systemic toxicity profile (120,121). Ovarian cancer ascites is rich with cytokine expression and the study of the ascitic fluid should help to better understand the immune interactions between tumor and host which is complex. A recent analysis showed ascites to be high in pro-inflammatory cytokines IL-6, IL-8 and the immune suppressive cytokines IL-10, CCL22 and TGF- β in most samples. Interestingly, high IL-6 expression predicted residual disease after debulking and was highest at recurrence (122).

Interferons

Although the full extent of action of IFN in patients with ovarian cancer is unknown, several mechanisms have been proposed: (a) stimulation of NK cells and macrophages, both of which are known to have antitumor properties (21); (b) antiangiogenic effects; and (c) inhibition of expression of dysregulated oncogenes (such as *HER2/neu*) and thereby improving the responsiveness of cisplatin-resistant cells (123). A Gynecologic Oncology Group Study evaluated administration of systemic IFN- α to patients with advanced ovarian cancer where patients with measurable disease showed a low response rate of approximately 10% (124). The role of intravenous IFN- α as a maintenance treatment after initial surgical resection and chemotherapy was also evaluated by a randomized phase III study and showed no benefit (125). Systemic IFN- α was also associated with frequent dose-limiting toxicity. Because of the poor response rate and frequent toxicity of systemic administration, further studies were focused on IP administration of IFN- α . Multiple clinical trials with IP IFN therapy were carried out leading to a randomized trial of adjuvant intraperitoneal α -interferon in stage III ovarian cancer patients who had no evidence of disease after primary surgery and chemotherapy by the Southwest Oncology Group (126). The trial was closed early but there was no difference between the study arms with regard to progression-free survival ($p = 0.56$). In cervical cancer, monotherapy with IFN- α had minimal activity (127). Studies evaluating intralesional interferon in HPV associated diseases (cervix and vulvar cancer) have waned as directly targeted immunologic approaches against the virus have emerged. Nonetheless, a recent study utilizing intralesional IFN = α 2 b in high grade cervical intraepithelial neoplasia showed a 60% response rate. Treated patients also expressed more Th1 (IFN- γ , TNF- α , IL-2) cytokines,

with a significant reduction in the viral load of high-risk HPV ($p = 0.0313$) (128).

Interleukin-2

IL-2 is a T-cell growth factor that plays a central role in the immune system with data showing IL-2-induced CD4⁺ T cell expansion in patients with HIV infection (129) as well as clinical responses in renal cell cancer and malignant melanoma resulting in an indication for treatment by the U.S. Food and Drug Administration for these tumors (120,121). It has been shown to activate tumor-associated macrophages and upregulate IFN-stimulated genes (130). Based on the toxicity of intravenous IL-2 administration, studies in ovarian cancer focused on IP administration. A phase I-II study (131) of IP IL-2 in patients with laparotomy-confirmed persistent or recurrent ovarian cancer after ≥ 6 courses of prior platinum-based chemotherapy had shown an overall response rate of 25.7%, with an overall 5-year survival probability of 13.9%. A more recent study shows that IP IL-2 administration in patients with ovarian cancer increases CD4⁺CD25⁺ high T-cells which highly express FOXP3 and suppress Treg cells. This suggests that IL-2 has a critical role in maintaining the Treg pool as well as enforcing Treg cell tumor trafficking in humans and may lend itself to combination studies of other agents targeting different immune checkpoints (132,133). A disadvantage of frequent administration of intravenous high-dose IL-2 is the occurrence of dose-limiting side effects. Therefore, delivery of IL-2 from an expression plasmid has been evaluated for the treatment of ovarian cancer. IP treatment of ovarian tumors with an IL-2-expressing plasmid resulted in an increase in local IL-2 levels, a change in the cytokine profile of the tumor ascites, and a significant antitumor effect in a mouse model (134). A recent *in vitro* study in colorectal cancer showed the ability of plasmids expressing murine IL-2 to enhance the antitumor activity of viral vector immunization against a cancer mucosa antigen showing the tolerability and possibility of combining plasmid-derived IL-2 production with other immunotherapeutic strategies as well (135).

Interleukin-12

IL-12 is a cytokine mainly produced by activated monocytes, tissue macrophages, and B cells. It can induce IFN- γ and together with IL-2 becomes a potent activator of cytotoxic T lymphocytes and NK cells (136,137). Whereas IL-4 and IL-10 mediate the development of Th2-type immunity, IL-12 initiates the differentiation to the Th1 phenotype. In addition, IL-12 production can be negatively or positively regulated by cytokines. For example, IL-10 and IL-4 have been shown to inhibit the production of IL-12 (138), whereas IL-2 and IFN- α enhance its production. In addition, IL-12 has potent antimetastatic and antitumor effects in several murine tumor models, as well as in human tumor cells *in vitro* and *in vivo* (139). Ascitic IL-12 had been shown to be an independent prognostic factor for adverse outcome in ovarian cancer (140) though later there was uncertainty over this finding as a result of a possible statistical flaw (141). A phase II GOG clinical trial (142) evaluated intravenously administered recombinant human IL-12 in patients with recurrent or refractory ovarian cancer. Myelotoxicity and capillary leak syndrome were the major adverse events. Partial response rate was on 3.8% with no complete responders. Recent focus has shifted to evaluating the administration of IL-12 expressing DNA. Two studies have evaluated this strategy in patients with malignant melanoma with patients showing response of greater than 30% in 5 of 12 patients receiving intratumoral injections; or CR in 2 of 19 and PR or SD in 8 of 19 patients using electroporation of plasmid coding IL-12. More investigation in this area including other tumor types is warranted and ongoing (143,144).

ANTIBODY MEDIATED THERAPY OF CANCER

Antibodies are the primary mechanism for eliminating infectious pathogens from the bloodstream. The effect of most commonly used vaccines against infectious agents is thought to be primarily a consequence of antibody induction with subsequent complement mediated inflammation and cytotoxicity (145). In addition, tumor antigen-specific autoantibodies are found in the sera of patients with solid tumors and generally increase with tumor burden (146,147). As one example, the presence of p53 autoantibodies was detected in 41.7% of patients with serous cancer, and detectable p53 antibodies were associated with improved overall survival ($p = 0.04$; HR = 0.57; 95% CI, 0.33, 0.97) (148). It is unknown whether this finding represents a biomarker for prognosis, or if the antibodies exert immunologic control of tumor. Another example is found in the presence of natural antibodies (i.e., prior to vaccination or administration) in paraneoplastic syndromes. In a series of 100 patients with small cell lung cancer, patients with autoantibodies causing the Lambert-Eaton myasthenic syndrome had improved survival (19.6 months) versus those who were antibody negative (8.9) (149). In platinum resistant ovarian cancer patients, another study showed that anti-MUC1 IgM antibodies correlated with overall survival at both early ($p = 0.052$) and late ($p = 0.009$) time points (150). These results provide the possibility that functionally effective antibodies may confer a survival advantage. The possibility that these represent a biomarker for better outcome instead cannot be excluded from this data. The ability of antibodies to mediate protection from tumor recurrence has also been suggested in experimental animal models (151). The administration of monoclonal antibody 3F8 against GD2 or induction of GD2 antibodies by vaccination after challenge with EL4 lymphoma (which expresses GD2) showed prolonged survival in mice receiving antibody ($p < 0.004$) or vaccination ($p < 0.008$) (151). Trials in gynecologic cancers have included the administration of murine or humanized antibodies directly targeting tumor associated antigens, indirect approaches utilizing anti-idiotypic antibodies, or antibodies conjugated to radionuclides, cytokines, or other immunotoxins. The greatest success in the antibody mediated treatment of cancer to date has come from a series of monoclonal antibodies against antigens expressed at the cell surface of cancer cells with clinical efficacy in both the advanced disease and adjuvant settings. Monoclonal antibodies are produced by hybridoma cells. They have evolved from simple murine derived antibodies with recombinant

engineering techniques to now permit monoclonal antibodies of various sizes, configuration, valence, and target effector functions (152). Examples with proven efficacy continue to grow to include an ever increasing list such as rituximab, ibritumomab, and tositumomab for B-cell lymphomas; gemtuzumab for acute myelocytic leukemias; alemtuzumab for chronic lymphocytic leukemias; cetuximab for colorectal and head and neck squamous cell carcinomas; and trastuzumab for breast cancer (152,153). A variety of mechanisms of action have been postulated: (a) monoclonal antibodies can mediate effector cells by having an activating or suppressive function in pathways such as with CTLA-4 (51), (b) they may target tumor supportive molecules such as VEGF with bevacizumab (154), or (c) they may recognize tumor specific receptors and by binding may activate or repress signaling pathways. Preclinical studies suggest that antibodies may have the most efficacy in the adjuvant setting. Since many gynecologic cancer patients are initially rendered free of detectable disease by surgery and/or chemotherapy after initial diagnosis, the administration of effective mAbs or vaccines with antibodies as part of the effector repertoire would have broad applicability. There are a variety of potential antigen targets for antibodies on gynecologic cancers. Screening for this purpose was traditionally limited to surface antigens since antibodies recognize antigens primarily at the cell surface. A previous study screened a series of 40 mAbs against 25 antigens common antigens that are potential targets for antibody mediated immunotherapy as listed in Table 15.3 (66,155,156). The antigens expressed by ovarian and endometrial cancers are similar, and quite different from those expressed by melanomas, and similar to, although not the same as, those expressed by prostatic cancers. The 18 excluded antigens (including CEA and *HER2/neu*) were expressed in 1 or 0 of 5 specimens. The expression of these antigens on normal tissues is essentially restricted to apical epithelial cells at luminal borders, a site that appears not to be accessible to the immune system. In addition to these overexpressed tumor associated antigens, other targets have included over-expressed growth-factor receptors (e.g., *HER2/neu* [erbB2], epidermal growth-factor receptor [EGFR], vascular endothelial growth factor [VEGF]); and mutated tumor-suppressor genes (e.g., p53 and *BRCA-1*). Binding of mAb to these antigens may have antitumor effect generated through a variety of possible mechanisms including: (a) antibody-mediated recruitment of human effector mechanisms *in situ*, ADCC against the tumor cells; (b) development of tumor-specific cytotoxic T lymphocytes (CTLs); (c) activation of the complement system; (d) stimulation of granulocytes cytotoxic to the cancer cells; and (e) induction of an anti-idiotypic antibody that can elicit active immunity.

Table 15.3 Potential Antigens for Antibody Directed Therapy

^bFrom Federici MF, et al. Selection of carbohydrate antigens in human epithelial ovarian cancers as targets for immunotherapy: serous and mucinous tumors exhibit distinctive patterns of expression. *Int J Cancer* 1999;81(2):193–198.

^cFrom Kabawat SE, et al. Immunopathologic characterization of a monoclonal antibody that recognizes common surface antigens of human ovarian tumors of serous, endometrioid, and clear cell types. *Am J Clin Pathol* 1983;79(1):98–104.

The extensive expression of CA-125 in over 80% of serous and endometrioid ovarian cancers has been well documented since the early 1980s (157). Following the successful cloning of CA-125 and identifying it as a complex mucin, it has been termed MUC-16 (158,159). Multiple efforts to target MUC-16 as a logical target for immunotherapy are underway.

Antibody Conjugates

In an attempt to add to the efficacy of unconjugated antibodies, efforts have been made to optimize the antitumor activity by conjugating with radionuclides, toxins, cytotoxic drugs, or second antibodies. The choice of conjugates and specific antibodies is influenced by features such as antigen internalization, lysosomal degradation, shedding, and heterogeneity of expression. The mechanism can be complex in that for some internalization is a prerequisite for cellular toxicity; while in others it may result in reduced efficacy and increased host toxicity due to intracellular catabolism (160).

Radionuclides

A variety of radionuclides have been conjugated with antibodies for imaging and treatment. The optimal radionuclide for cancer therapy is dependent on many factors (161). Radioconjugates with β (i.e., ^{131}I and ^{90}Y) and α (i.e., ^{211}At and ^{212}Bi) emitters have been proposed for regional therapy of peritoneal implants (162). Estimates of dosimetry suggest that adequate therapy (i.e., 20 Gy) could be delivered to tumors with a depth less than 300 μg using ^{211}At , less than 0.1 cm using ^{131}I , and less than 1 cm using ^{90}Y when conjugated to antibodies. The relatively low radiation dose makes the intraperitoneal delivery route attractive in order to put the source close to the tumor implants in the case of ovarian cancer. Delivery of effective radiation dose is greatly influenced by the extent of tumor binding, depth of tumor penetration, catabolism, and relative distribution between tumor and normal tissues. Antibody-radionuclide conjugates have been successfully developed for non-Hodgkin's lymphoma resulting in drug approvals with CD20 targeted agents (163). Randomized clinical data in ovarian cancer are sparse with two larger studies having been reported. A randomized trial of 251 patients with Stage 1a or 1b grade 3, or 1c, or 2 ovarian cancer with no macroscopic residual disease were randomized to intraperitoneal radioactive chromic phosphate (32P) versus cisplatin and cyclophosphamide chemotherapy. The cumulative incidence of recurrence at 10 years was 35% (95% CI, 27%–45%) versus 28% (95% CI, 21%–38%) favoring chemotherapy ($p = \text{ns}$). The toxicity profile of 32P was worse (164).

The SMART study was a large randomized study which evaluated intraperitoneal yttrium-90-labeled HMFG1 murine monoclonal antibody in patients with ovarian cancer after a surgically defined complete remission. The MUC-1 antigen that ^{90}Y -muHMFG1 is directed towards is well established as an immunotherapy target and is overexpressed on 90% of adenocarcinomas including that of ovarian cancer. The phase II data supporting the use of ^{90}Y -muHMFG1 administered intraperitoneally in patients in first remission was promising with a Cox model estimate of 10 year survival at 70% compared to 32% of case matched controls ($p = 0.003$) (165). Patients were stratified using a second surgical assessment where disease status at second look remains a powerful predictor of ultimate progression-free and overall survival (166). Despite the strong preclinical and clinical data supporting this approach, at a median followup of 3.5 years, relapses occurred in 98 versus 104 patients ($p = \text{ns}$). While there is no randomized evidence supporting efficacy of radioconjugates in gynecologic malignancies to date, the number of candidate agents for investigation continues to increase and earlier phase trials are ongoing.

Immunotoxins, Drugs, and Cytokines

Drugs, toxins, and cytokines conjugated to mAbs have been evaluated in numerous cancers. Immunotoxins incorporate an antibody-binding domain and a toxin joined by a chemical cross-linker, peptide, or disulfide bond. The specific targeting afforded by mAbs and the relative potency of the toxin moiety present potential therapeutic advantages. Early conjugates, which have generally not been successful, linked antibodies to standard anticancer drugs such as doxorubicin or vinblastine. It is generally not possible to deliver comparable levels of cytotoxic agents as intravenous administration using this approach. This field is advancing by replacing murine antibodies with humanized versions and conjugating agents that are both specific and functional at lower doses (167). Multiple agents are being evaluated though none have proven efficacy in gynecologic tumors to date.

Other Selected Clinical Trials with Monoclonal Antibodies

Monoclonal Antibodies Targeting CA-125

CA-125, a tumor-specific antigen that is found in 97% of patients with late-stage ovarian cancer, was first described by Bast et al. as an antigen that is elevated in the serum of patients with epithelial ovarian cancer (157). CA-125 has been cloned and identified as the mucin MUC-16 (168), as shown in Figure 15.2. Studies have shown that MUC-16 has a variety of functions and contributes to ovarian cancer cell growth, survival and invasiveness (169). Recent data suggest that expression is extended to digestive tract adenocarcinomas, and moderate expression likewise correlates with poor survival ($p < 0.001$) (170). The sheer size of the MUC-16 complex has made selecting appropriate sequences for incorporation into vaccines difficult, and initial studies focused on antibodies which could be raised against CA-125.

Monoclonal antibodies including anti-idiotypic antibodies have been used as CA-125 targets. The historical rationale for

FIGURE 15.2. Proposed MUC-16 structure.

an anti-idiotypic vaccine was an attempt to augment both antibody and T-cell responses by using antibody facsimiles of the native antigens with the goal of overcoming poor immunogenicity. Tumor-associated antigens are traditionally weakly immunogenic as the large majority of them in humans are nonmutated self-antigens. This approach attempted to present the desired epitope to the now tolerant host in a different molecular environment but the problem with many tumor antigens is that they are ill-defined chemically and difficult to purify and produce (171). The “immune network hypothesis” set out to transform epitope structures into idiotypic determinants expressed on the surface of antibodies. It was originally proposed in the 1970s (172), and assumes that immunization with a given antigen will generate the production of antibodies against this antigen (termed Ab1). Ab1 can generate anti-idiotypic antibodies against Ab1, termed Ab2. Some of the anti-idiotypic antibodies (Ab2 β) express the internal image of the antigen recognized by the Ab1 antibody and can be used as surrogate antigens. Immunization with Ab2 β can cause the production of anti-anti-Id antibodies (termed Ab3) that recognize the corresponding original antigen identified by Ab1 (285,286). (Since Ab3 can have Ab1-like reactivity, it is also called Ab1' to distinguish it from the original Ab1.) Two mAbs against CA-125 have been extensively evaluated and recently reported in a series of clinical trials.

Oregovomab

Oregovomab (MAb B43.13) is an IgG1k subclass murine monoclonal antibody that binds with high affinity (1.16 X 1010/M) to circulating CA-125. CA-125-specific antibodies, T helper cells, and cytotoxic T cells are produced demonstrating both a humoral and cellular response (173–175). Retrospective and prospective phase II trials have associated a longer overall survival with immune response (176,177). A randomized placebo controlled trial of 145 patients with stage III or IV epithelial ovarian cancer receiving IV oregovomab in first clinical remission showed a median time to progression from randomization post front-line therapy of 13.3 months for patients receiving oregovomab versus 10.3 months for those receiving placebo ($p = 0.71$). In a subgroup of patients (*maximum* of 2 cm residual at debulking, CA-125 at *maximum* of 65 U/ml before third cycle, and CA-125 at *maximum* of 35 U/ml at entry), time to progression for patients receiving oregovomab versus placebo was 24 months versus 10.8 months (HR, 0.543; 95% CI, 0.287–1.025) (178). Appropriately, using the eligibility criteria of the subgroup as hypothesis generating, the investigators prospectively enrolled 354 patients in first clinical remission in a recently reported phase III trial. Median time to progression was 10.3 months (95% CI, 9.7–13.0 months) for the oregovomab group, and 12.9 months (95% CI, 10.1–17.4 months) for the placebo group ($p = 0.29$), showing no benefit to oregovomab immunotherapy (179).

Abagovomab

Abagovomab is an anti-idiotypic antibody produced by a mouse hybridoma and generated against OC125 (180). It recognizes the tumor associate antigen CA-125. The induction of a specific immune response (both humoral and cellular) was confirmed in preclinical studies, and a phase I-II trial with 119 patients showed an association between prolonged survival in ovarian cancer patients who demonstrated an Ab3 antibody response (68%) to vaccination versus those that did not (23.4 months versus 4.9 months). No significant adverse events were noted (181,182). Subsequent phase I studies confirmed safety, efficacy of the subcutaneous route, and suggested that longer vaccination sequences produced more robust immune responses (182,183). These data provided the rationale for a phase III randomized trial. Patients with FIGO stage III or IV ovarian cancer in

complete clinical remission after primary surgery and platinum/taxane based chemotherapy were randomized 2:1 in a phase III, double blinded, placebo controlled, multicenter study. Abagovomab 2 mg or placebo was given as 1 ml sc every 2 weeks for 6 weeks (induction phase), then every 4 weeks (maintenance phase) until recurrence or up to 21 months after randomization of last patient. Primary endpoint was recurrence free survival; secondary end-points were overall survival and immunological response. The characteristics of 888 patients were: mean age, 56.3 years; ECOG PS *maximum* of 1 in more than 99%; serous papillary subtype in 81.5%; FIGO stage III in 85.9%; CA-125 ≤ 35 U/ml after the third cycle FLCT in 80.9% of patients. The mean exposure to study treatment was 449.7 ± 333.08 days. The hazard ratio of recurrence free survival for treatment group using (≤ 1 cm, > 1 cm) tumor size categorization was 1.099 (95% CI, 0.919–1.315; $p = 0.301$). The hazard ratio of overall survival for the treatment group using tumor size catheterization (≤ 1 cm, > 1 cm) was 1.150 (95% CI, 0.872–1.518, $p = 0.322$). The most frequently reported type of adverse event was an injection site reaction reported in 445 (50.2%) patients overall followed by injection site erythema and fatigue which are reported in 227 (25.6%) and 212 (23.9%) patients overall respectively. By the final study visit, the median Ab3 levels were 493,000.0 ng/ml which indicated a robust immunologic response. In conclusion, Abagovomab given as repeated monthly injections was safe and induced a measurable immune response but its use did not result in a prolonged progression-free survival (184).

There was a traditional notion that combining immunotherapy and chemotherapy may not be desirable due to the possible immunosuppressive nature of cytotoxic chemotherapy. However, emerging data continues to show that chemotherapy selectively eliminates immunosuppressive lymphocyte populations, and thereby may beneficially alter the characteristics of an immune response (101). A study with concurrent oregovomab and chemotherapy in recurrent epithelial ovarian cancer supports the idea that favorable specific immune responses could be generated in the presence of concurrent chemotherapy (185). The idea of combining chemotherapy and immunotherapy remains one to be clinically evaluated.

Monoclonal Antibodies Targeting ERBB1 (EGF), ERBB2 (HER2/neu), and VEGF

The epidermal growth factor receptor (EGFR) has been a frequent target for cancer treatment development in the past decade. The EGF tyrosine kinase inhibitor gefitinib had a minimal objective single agent response rate of 4% in unscreened patients with ovarian cancer (9% in EGF + patients). The patient with the only objective response had a mutation in the catalytic domain of EGFR, and the frequency of mutation in this study was 1/32 or 3% (186). The anti-EGFR antibody matuzumab, was also tested in patients with recurrent, EGFR-positive ovarian, or primary peritoneal cancer in a multi-institutional single-arm phase II trial of 75 patients, and showed no significant clinical activity as a monotherapy. These data suggest that anti-EGF targeted therapy as a single agent in ovarian cancer is relatively inactive, but dual inhibitors and combination therapy with chemotherapy are still being investigated (187).

HER2 overexpression appears inversely correlated with overall survival in patients with ovarian cancer when considered in univariate and multivariate analysis among other usual prognostic factors (188). The most significant treatment experience in patients with recurrent or refractory ovarian or primary peritoneal cancer in a Gynecologic Oncology Group Study screened 837 tumor samples for HER2 expression, and showed the required 2+/3+ expression occurred in only 95 (11.4%) patients (189). Forty-five patients were entered into the study with an overall response rate of 7.3% with a median progression-free

interval of 2.0 months. Based on infrequent HER2 expression, and the low rate of objective responses, the clinical value of single-agent trastuzumab appears limited in these patients. The potential role on combination with chemotherapy is unknown but the broad applicability will be limited by the frequency of expression. Pertuzumab is a recombinant humanized monoclonal antibody binding to the HER 2 dimerization domain which stoically blocks the pocket required for dimerization (190). A randomized phase II trial evaluated pertuzumab in platinum sensitive disease with a comparison of platinum based therapy with or without pertuzumab. Results are pending publication. Studies are simultaneously looking to characterize the affected molecular pathways particularly in patients with response as colateral signaling may play an important role in further tumor growth (191).

The growth and metastasis of malignant neoplasms require the presence of an adequate blood supply, and recent data have confirmed the therapeutic potential of multiple antivascular strategies. The role of bevacizumab and other antivascular agents are discussed in the appropriate chapters regarding the treatment of patients with ovarian cancer.

Monoclonal Antibodies Targeting EPCAM (Antiepithelial Cell Adhesion Molecule)

The tri-functional antibody catumaxomab (EPCAM X anti-CD33) has been evaluated in patients with malignant ascites (192). The phase II/III trial randomized patients to standard paracentesis or paracentesis with antibody delivered via the intraperitoneal route. Puncture free survival was longer in the catumaxomab group (median 46 days) than the control group (median 11 days) with hazard ratio = 0.254, $p < 0.0001$. There was a correlation between humoral response and clinical outcome (193). Additional study is ongoing.

Monoclonal Antibodies Targeting Antigens in Cervical and Endometrial Cancer

There are no approved antibody strategies targeting antigens in cervical or endometrial cancer to date. Vascular endothelial growth factor targeted approaches are ongoing in patients with cervical carcinoma and endometrial cancer, and these are discussed in the appropriate chapters. Epidermal growth factor targeted approaches have also been evaluated in patients with cervical cancer. The epidermal growth factor receptor is overexpressed in 85% of patients with invasive cervical cancer (194). Cetuximab is a chimeric IgG1 mAb that antagonizes normal ligand receptor interactions. A phase II trial by the Gynecology Oncology Group evaluated single agent cetuximab in 38 patients. No clinical responses were detected (195). Cetuximab was also evaluated in 76 patients in combination with cisplatin chemotherapy in treated and chemotherapy naïve patients. Response rates of 9% and 16% respectively were seen with no evidence for a benefit of cetuximab over cisplatin alone (196).

(phenotype and polarization) of antibody and T-cell responses; and (c) developing combinatorial approaches with adoptive T cell or immunomodulation therapy to maximize activation and function of vaccine-primed effector cells *in vivo*.

Vaccines Designed Primarily to Generate Antibody Responses

Most current vaccines seek to generate cellular responses (often with an accompanying humoral or integrated response). However, based on the cell surface target antigen selection process appropriate for antibody recognition described above, and advances in the chemical and enzymatic synthesis of carbohydrate and glycopeptide antigens and optimization of adjuvant use, the exploration of a variety of synthetic antigen vaccines with antibody production as the endpoint was feasible (203–205). After defining targets to include GM2, Globo-H, Lewis^x, sialyl Tn (STn), Tn, Thompson Friedreich antigen (TF), and mucin 1 (MUC-1) (66,155,156,206), a series of phase I univalent trials were performed. The most immunogenic approach was identified to include chemical conjugation of the antigen to a highly immunogenic carrier protein (keyhole limpet hemocyanin (KLH) plus the use of a potent immunological adjuvant such as the saponin QS-21 or OPT-821 (207). Preclinical data supported the hypothesis that polyvalent vaccines would likely be required due to tumor cell heterogeneity, heterogeneity of the human immune response, and the correlation between overall antibody titer against tumor cells and antibody effector mechanisms (208). Preclinical models further showed that a heptavalent KLH conjugate plus QS-21 vaccine induced antibody titers comparable to those induced by monovalent vaccines containing Tn, STn, TF, MUC-1 and Globo-H. Lower titers were produced against Lewis^x and GM2 (209). Some antigens have required modification for optimal immunogenicity resulting in trimers or clusters (c) of Tn, STn, and TF rather than unmodified monomers (210,211). A pilot trial of a heptavalent vaccine-KLH conjugate plus QS-21 in patients with epithelial ovarian, fallopian tube, or peritoneal cancer in either a first (following persistence and additional treatment), second, or third remission (212). The administered heptavalent vaccine contained GM2 (10 µg), Globo-H (10 µg), Le^x (10 µg), Tn-MUC1 (3 µg), Tn(c) [clusters] (3 µg), STn(c) (3 µg) and TF(c) (3 µg) individually conjugated to KLH and mixed with adjuvant QS21 (100 µg). Vaccinations were administered at weeks 1, 2, 3, 7, and 15. ELISA assays were tested against the following target antigens: Tn-MUC1-32mer, GM2, Globo-H ceramide, Le^x ceramide, desialated ovine submaxillary mucin (DOSM) expressing Tn, OSM expressing STn, and desialated porcine submaxillary mucin (DPMSM) expressing TF. IgM and IgG antibody titers were measured by ELISA as described previously (213–215). Fluorescent-activated cell-sorting (FACS) was performed as previously described to demonstrate antibody binding to the cell surface of the cell line MCF-7. MCF-7 was chosen as it is known to express each of the 7 antigens (213–215). Side effects were limited to fever and local injection site reactions which were self limited. After immunization median IgM titers were as follows: Tn-MUC-1 1:640 (IgG 1:80), Tn 1:160, TF 1:640, Globo-H 1:40, and STn 1:80. Eight of nine patients developed responses against at least three antigens. FACS and CDC analysis showed substantially increased reactivity against MCF7 cells in 7/9 patients, with some increase seen in all patients (212). This has led to Gynecology Oncology Group Trial 255 (NCT00693342) which is a randomized trial in ovarian cancer patients with second or third complete clinical remission receiving either the adjuvant alone (OPT-821) versus the multivalent antigen construct + OPT-821. The endpoint is the proportion of patients' disease free at 12 months (35% vs. 50%) and accrual is currently ongoing with a target accrual of 154 patients.

CANCER VACCINES

Vaccines remain a backbone in the approach to ovarian cancer immunotherapy (197–201). Similar to experiences in other immunogenic tumors (202), vaccines have shown limited efficacy as monotherapy in patients with advanced recurrent disease. Clearly, much work is required to improve their performance. Current efforts to improve vaccines are directed broadly towards (a) optimizing the choice of antigens; (b) improving vaccine delivery systems to maximize the magnitude and quality

Vaccines Primarily Designed to Produce Cellular or Integrated Responses

There are a wide range of options for augmenting the immunogenicity of the antigenic targets for T-cell immunity and this remains the primary goal for tumor immunotherapy (216,217). This now includes the possibility of genetically modifying T cells by themselves to express both tumor associated antigens and dendritic cell activating molecules (217). For the antigens, the options include (a) the full proteins or MHC-restricted peptides modified by amino acid substitutions to increase immunogenicity; (b) genes or mini-genes for these proteins or peptides used as DNA vaccines; or (c) genes expressed in viral or bacterial vectors. Co-stimulatory molecules, cytokines, or molecules targeting antigens to particular processing compartments can be incorporated into these vaccines. DNA vaccines are appealing in this regard because of ease of production, versatility, and adaptability to such combinations (198). Most of these approaches can also be applied to expressing these antigens in antigen-presenting cells, such as dendritic cells, that are then used to vaccinate the patient. Furthermore, since many tumor-rejection antigens detected by T cells in experimental animals are individually unique (mutated), a variety of individualized vaccines are being tested. Whole-cell vaccines can be prepared from a specific patient (if accessible tumor is available) and immunogenicity may be increased by the use of an immunologic adjuvant and transduction with genes for cytokines or co-stimulatory molecules, or treatment with haptens such as dinitrophenyl (DNP) (218). Other approaches attempting to increase the immunogenicity of unique and shared antigens include the use of heat shock proteins that may carry the full range of cancer peptides, and DNA or messenger RNA vaccines that may be obtained from smaller biopsy specimens (219).

An ever increasing number of antigen targets for vaccines producing cellular or integrated responses is being identified. Common antigens shared by ovarian or endometrial cancers from different patients are KSA, MUC-16, WT1, CEA, MUC-1, HER2/neu, and cancer-testis antigens (including the MAGE family) and NY-ESO-1. None of these cancer antigens defined as targets for T cells to date is a perfect candidate for the majority of patients due to (a) overexpression on less than 50% of ovarian or endometrial cancers (HER2/neu, CEA, and the cancer-testis antigens) and (b) wide expression (though at lower levels) on normal tissues (KSA, CEA, HER2/neu, MUC-1) (220). MUC-16 for ovarian cancers and human papillomavirus (HPV)-related antigens for cervical cancer are especially strong candidates at this time because of their widespread expression on the respective cancers and restricted expression on normal tissues.

Molecular analysis of endometrial carcinomas has identified a variety of proteins that may serve as target antigens for vaccine-based therapy. For example, over-expression of HER2/neu has been correlated with advanced disease and poor outcome in both adenocarcinoma and uterine papillary serous carcinoma (221). More recent reports have implicated alterations in the hMLH1, p16 (ink4a) (p16), and *PTEN* genes as promoters of carcinogenesis, as well as over-expression of the *SART-1* gene, which encodes the SART-1 tumor antigen that is recognized by HLA-A26-restricted cytotoxic T lymphocytes (32% of tested specimens) (6).

Dendritic-Cell Approaches

Dendritic cells (DC) are phenotypically distinct, potent antigen-presenting cells well suited for vaccine strategies (222). They are found throughout the body, particularly at the portals of entry for infectious organisms, such as in the epidermis and other epithelial surfaces. Cancers may be ineffective at attracting DCs, may attract the wrong type of DCs, or may attract immature

DCs that induce tolerance. It has been observed that ovarian carcinoma cells express high levels of the chemokine SDF-1 that attracts a subset of DC precursors with capacity to differentiate into plasmacytoid DCs, which are implicated in immune suppression through induction of IL-10 by T cells. Myeloid DCs, which are more effective at inducing immune responses, were not detected (223). Also, plasmacytoid DCs have been implicated in inducing a set of CD8+ regulatory T cells in ovarian carcinoma (224). DCs from patients with ovarian cancer can be matured *ex vivo* to activate T cells producing IFN- γ in response to autologous tumor cell lysates, but not cytotoxic T cells (225). Ovarian carcinoma cell lines can directly inhibit maturation of DCs (226). These results and many others suggest that DCs from cancer patients can be defective at fully activating T cells. Studies have shown that myeloid DCs from tumor or draining lymph nodes of ovarian carcinoma express B7-H1, a molecule in the B7 family implicated in inhibiting immune responses (92). Blockade of B7-H1 led to marked increases in T-cell responses. Multiple animal studies have demonstrated CTL-mediated protective immunity and even regression of established tumors with the administration of antigen pulsed dendritic cells (227). A variety of approaches have been considered with regard to antigen type and loading techniques to include recombinant or fusion proteins (227), peptides as tumor antigen-derived CTL epitopes (228), DC-tumor cell hybrids (229), HLA-restricted antigens (230), and autologous antigens from tumor cell lysates and apoptotic tumor cells as discussed below. A number of other antigen sources are also possible for DC-based treatment of ovarian cancer.

SELECTED CLINICAL TRIALS

NY-ESO-1 Vaccines

Cancer/testis (CT) antigens: The first human cancer antigen was identified in a melanoma patient by a strategy called the T cell epitope cloning technique. This antigen was named MAGE-1 (melanoma associated gene 1) (231). Subsequently, a family of MAGE related genes (e.g., *MAGE-1*, *MAGE-3*, *BAGE*, *GAGE*) was identified in the same patient and later also in others, which encode antigens that are expressed in melanomas and several other tumors, but not in normal tissues except testis. At present, over 100 CT genes or gene families have been found with the following two distinguishing features: (a) mRNA expression in testis and cancer and (b) no or highly restricted mRNA expression in normal adult somatic cells.

Approximately 50% of the currently known CT genes reside on chromosome X (CT-X), where they constitute over 10% of the coding sequence and appear to be under strong positive selection during evolution. Many questions regarding CT genes remain open, including the biological function of their protein products, and the elucidation of factors that control their expression in normal tissues and cancer. The frequency of CT antigen expression in many cancer types ranges from 5% to 40%, with exceptionally high expression of individual CT antigens in certain cancers, e.g., MAGEC1/CT7 in 70% of myeloma and NY-ESO-1 in 80% of synovial sarcoma.

The reasons for the aberrant expression of CT antigens in cancer are currently unknown. Nevertheless, the fact that the expression of these antigens is restricted to cancers, gametes, and trophoblast suggests a link between cancer and gametogenesis. Although possible mechanisms include global demethylation and histone deacetylation, the induction of a "gametogenic" program in cancer has also been proposed (232). Emerging evidence also suggest that NY-ESO-1 and some additional CT antigens, may be selectively expressed by cancer "stem cells." Therefore, the development of strategies to target CT antigens

Table 15.4 Expression and Immunogenicity of Selected CT Antigens in Ovarian Cancer

CT antigen	mRNA	IHC	ELISA
NY-ESO-1 (233)	43%	43%	25%
SPAG9 (312)	90%	—	67%
OY-TES-1 (313)	69%	69%	10%
LAGE-1 (233)	21%	—	25%
Sp17 (314)	83%	—	—
SSX (315)	26%	—	2.3%
AKAP-3 (316)	58%	—	—
HOM-TES-14 (SCP-1) (317)	15%	0%	—

in ovarian cancer could have potential therapeutic benefit. The expression and immunogenicity of selected CT antigens is presented in Table 15.4.

Among CT antigens, NY-ESO-1, initially defined by serologic analysis of recombinant cDNA expression libraries (SEREX) in esophageal cancer, is particularly immunogenic, eliciting both cellular and humoral immune responses in a high proportion of patients with advanced NY-ESO-1 expressing ovarian cancer (233). The immunogenic NY-ESO-1 epitopes recognized by T lymphocytes appear to be clustered around the central part of the NY-ESO-1 protein. A number of NY-ESO-1 based clinical trials have been conducted in ovarian cancer patients, and additional trials are ongoing. Details of studies in progress are as follows:

A pilot clinical trial of NY-ESO-1DP4 p157-170 (NY-ESO-1DP4), a peptide of potentially dual MHC class I and class II specificities, in patients with epithelial ovarian, fallopian tube or primary peritoneal carcinoma whose tumors express NY-ESO-1 or LAGE-1: In this trial, 18 ovarian cancer patients who were NED after therapy for primary or recurrent disease were vaccinated with NY-ESO-1 epitope, ESO₁₅₇₋₁₇₀, a naturally processed helper epitope that is recognized by CD4⁺ T cells in the context of HLA-DP4 (i.e., HLA-DPB1*0401 and *0402) (234). This NY-ESO-1 epitope has HLA-A2 (ESO₁₅₇₋₁₆₅) (235) and HLA-A24 (ESO₁₅₈₋₁₆₆) (236) motifs embedded in its natural sequence. The study tested whether active immunization with ESO₁₅₇₋₁₇₀ would elicit NY-ESO-1-specific CD4⁺ and CD8⁺ T-cell responses in ovarian cancer patients with minimal disease burden. The peptide SLLMWITQC (100 µg) was mixed with 0.5 mL of Montanide ISA-51, given by s.c. injection once every 3 weeks for a total of 5 to 15 doses. There was induction of CD4⁺ T-cell responses in 83% of patients; and CD8⁺ T-cell responses in 60% of HLA-A2⁺ patients; but in none of the five HLA-A24⁺ patients. Although the majority of patients were heavily pretreated, the median time to disease progression/recurrence from start of vaccination was 19.0 months (237).

Phase I study of NY-ESO-1b peptide and montanide ISA-51 vaccination of patients with epithelial ovarian cancer in high-risk first remission: This study enrolled nine patients to assess the primary and secondary end points of toxicity and immunogenicity. Eligible patients were those with high-risk epithelial ovarian cancer (defined by suboptimal initial debulking surgery, failure to normalize CA-125 after 3 cycles of chemotherapy, or positive second-look surgery) in cCR, as documented by CT scan and CA125 after completion of primary surgery and

chemotherapy. The HLA-A*0201-specific NY-ESO-1b peptide SLLMWITQC (position 157-165; 100 µg) mixed with 0.5 mL of Montanide ISA-51 was given by s.c. injection once every 3 weeks for a total of 5 doses (week 1, 4, 7, 10, and 13). Three of 4 patients (75%) with NY-ESO-1-positive tumor showed T-cell immunity by tetramer and ELISPOT. Four of 5 patients (80%) with NY-ESO-1-negative tumor showed T-cell immunity by tetramer and/or ELISPOT. The median progression-free survival was 13 months (238).

Phase II study of recombinant vaccinia-NY-ESO-1 (rV-NY-ESO-1) and recombinant fowlpox-NY-ESO-1 (rF-NY-ESO-1) in patients with epithelial ovarian, fallopian tube or primary peritoneal carcinoma whose tumors express NY-ESO-1 or LAGE-1 antigen: This is the only reported phase II clinical trial of NY-ESO-1 vaccine therapy in ovarian cancer (239). The objective of the study was to test whether a priming immunization strategy with recombinant vaccinia-NY-ESO-1 (rV-NY-ESO-1), followed by booster vaccinations with recombinant fowlpox-NY-ESO-1 (rF-NY-ESO-1) will minimize the risk of progressive disease in advanced ovarian cancer patients, following their first line therapy. Integrated NY-ESO-1-specific antibody and CD4⁺ and CD8⁺ T cells were induced in a high proportion of the patients. The clinical results showed that (a) seronegative patients who remained seronegative but developed CD4 and/or CD8 T-cell responses and (b) seronegative patients who seroconverted and developed CD4 and/or CD8 T-cell responses demonstrated improved OS (median, 52.4 and 48.4 months, respectively) compared with other categories of patients (median, 14.5 months) ($p < 0.0001$).

Ongoing clinical trials to enhance NY-ESO-1 vaccine efficacy (<http://www.clinicaltrials.gov>): In an effort to enhance NY-ESO-1 vaccine efficacy, a number of novel approaches are undergoing clinical evaluation. These include:

(i) *The use of pox-viral vectors expressing NY-ESO-1 and TRICOM, TRIad of COstimulatory Molecules (B7-1, ICAM-1 and LFA-3, NCT00803569):* These 3 molecules are found on antigen-presenting cells. B7.1 (CD80) is a protein that interacts with T-cell ligands CD28 resulting in T-cell stimulation *in vitro*. ICAM-1 (CD56) is an adhesion molecule found on the surface of antigen-presenting cells that binds to the T-cell ligand leukocyte function-associated-antigen (LFA)-1. LFA-3 (human CD58) is a surface protein that binds to CD2 expressed on T-cell, resulting in T-cell stimulation and priming (240). Together, the use of TRICOM in pox-viral constructs has been shown to expand antigen-specific CD8⁺ T cells with superior functional avidity (241-243), leading to better tumor control.

(ii) *The use of novel adjuvant formulations to enhance magnitude of immune response (study of NY-ESO-1 overlapping peptides and immunoadjuvants montanide and Poly-ICLC, NCT00616941):* In this study, ovarian cancer patients in second or third remission were immunized with NY-ESO-1 peptides and a novel adjuvant, poly-ICLC. Polyriboinosinic-polyribocytidylic acid (poly I:C), a synthetic double-stranded RNA (dsRNA), is recognized by TLR3 and other intracellular receptors. It is expected that this approach will generate robust effector T-cell responses with significant potential for tumor control.

(iii) *Combination of NY-ESO-1 vaccination with a strategy to counteract immune escape due to antigen or MHC downregulation (NCT00887779):* In a completed protocol, the demethylating agent, decitabine was combined with chemotherapy and vaccine therapy in order to induce MHC and tumor antigen expression in tumors, and promote “antigenic” dose to effector T-cells.

(iv) *Combination of NY-ESO-1 vaccination with rapamycin as a strategy to generate memory T cells for durable tumor protection (NCT01536054):* In this study, vaccination is combined with rapamycin in various doses and schedules, in order to determine a regimen that best generates memory T-cell responses. The induction of memory T-cell responses is a key to prevent tumor

recurrence, but has been a major challenge for all tumor immunotherapy approaches. Recent studies indicate that inhibition of mTOR activity switches Tbet for Eomesodermin expression and slants CD8⁺ effector cells for memory precursor like phenotype (244–246). Moreover, *in vivo* murine studies have shown that sirolimus augments antigen specific vaccination by inducing a long lasting, tumor protective memory T-cell response. Therefore, this trial will test whether mTOR inhibition will condition vaccine induced T cells for enhanced persistence, antigen recall and tumor efficacy.

Granulocyte Macrophage Colony Stimulating Factor (GM-CSF) Secreting Tumor Vaccines

Granulocyte-macrophage colony-stimulating factor (GM-CSF) has a variety of properties desirable for vaccine production including enhancing immune responses by inducing the proliferation, maturation, and migration of dendritic cells and the expansion of both T- and B-cell lymphocytes (247). Its adjuvant response has shown the early elevation of inflammatory molecules such as IL-6, TNF- α , and monocyte chemoattractant protein-1 (MCP-1) followed later by IL-12 and IFN- δ production, among others (247). *In vitro* characterization of a GM-CSF-secreting vaccine was performed by genetically engineering UCI-107 (ovarian cancer cell line) to secrete GM-CSF by retrovirus-mediated gene transduction with the LXS retroviral vector containing the human GM-CSF gene and the neomycin resistance selection marker. A clone (UCI-107 GM-CSF-MPS) was extensively characterized and shown to secrete high levels of GM-CSF over 6 months of study (248). In human trials, a variety of studies have shown that vaccination with irradiated tumor cells engineered to secrete GM-CSF stimulates long-lasting immunity in murine models and in patients with metastatic melanoma. A phase I study evaluated patients with metastatic non-small cell lung carcinoma. A metastatic site was resected, processed to single-cell suspension, infected with a replication-defective adenoviral vector encoding GM-CSF, irradiated, cryopreserved, and then given intradermally at weekly and biweekly intervals. Vaccines were made successfully for 34 of 35 patients. Dendritic cell, macrophage, granulocyte, and lymphocyte infiltrates were elicited in 18 of 25 assessable patients. Five patients had stable disease ranging from 3 to 33 months; and one patient had a mixed response (249). This led to 2 randomized phase III trials (VITAL 1 and VITAL 2) in patients with prostate cancer evaluating the allogeneic GM-CSF secreting prostate cancer vaccine either in comparison to chemotherapy or in combination with chemotherapy (250). Both trials were closed early and futility analysis predicted < 30% chance of meeting primary endpoint. Efficacy has not been demonstrated in patients with gynecologic cancers.

Folate Receptor–Targeted Vaccines

Previous studies have identified the alpha isoform of the folate receptor (FR), which is a 38-kD GPI-anchored protein constitutively expressed at high levels in 90% of nonmucinous ovarian cancer and at low levels in normal tissues (251). The reason for over-expression is unknown, but one hypothesis is that over-expression provides an alternate folate-processing pathway to compensate for deletion of the tetrahydrofolate reductase gene that is deleted frequently in cancer cells (252). FR expression has been shown in preclinical models to confer a growth advantage in FR-transfected cells, which suggests a role for the receptor in the control of cell proliferation (253,254). The preferential over-expression of the folate receptor in malignant tissue has prompted the investigation of this antigen in several

preclinical immunization studies. Neglia et al. (255) evaluated FR- α cDNA after ligation into the VR1012 (Vical) expression vector under transcriptional control of the cytomegalovirus promoter. Purified plasma DNA was injected into BALB/c mice three times at 14-day intervals. At 10 days after the second injection, sera (100%) showed antibody titers against syngeneic C26 cells transduced with FR- α , but not against unmodified C26 cells. Specific cytotoxic T lymphocyte activity against FR- α -transduced C26 cells could be seen in splenocytes from all immunized animals. Challenge by subcutaneous injection with FR- α -transduced C26 cells (administered 10 days after third injection) showed a statistically significant delay in tumor growth (255). Further studies by Peoples et al. showed that both immunodominant E39 (folate-binding protein [FBP]) (194–202), and subdominant E41 (FBP) (246, 248–255), epitopes of human high-affinity FBP are presented by HLA-A2 in both ovarian and breast cancers (256). Tumor-associated lymphocytes stimulated with FBP peptides exhibit cytotoxicity not only against peptide-loaded targets but also against FBP-expressing epithelial tumors of different histologies. These studies provide motivation for proceeding to clinical trials with folate receptor targeted strategies.

The most developed clinical strategy evaluated Farletuzumab (MORAB-003), which is an anti-folate receptor monoclonal antibody derived from the optimization of the LK26 molecule using a whole cell genetic platform. Following optimization, it exhibits an affinity similar to the original murine LK26 antibody (–2 nM) and its tissue binding profile parallels that of the folate receptor antibody (257). A phase I study in 25 patients with platinum resistant ovarian cancer was dose finding, and showed stable disease in nine patients (258). An open label phase II study followed with patients receiving farletuzumab as single agent or in combination with platinum and taxane based therapy suggesting activity in combination with chemotherapy. Development has proceeded to the FAR 131 study (NCT00849667) which is a randomized phase III trial evaluating Morab-003 in combination with paclitaxel and carboplatin in patients with platinum sensitive disease. The final study results will define the activity of this antibody in patients with ovarian cancer. An alternative approach using dendritic cells transfected with mRNA encoded folate receptor is also being evaluated (259).

Muc-1 Targeted Vaccines

MUC-1 is a mucin family member that is generally expressed on the apical surface of epithelial cells (150). Increased serum MUC-1 ($p = 0.003$) and high MUC-1 antibody levels ($p = 0.052$) have been associated with worse prognosis. Autologous dendritic cells pulsed with mannan-MUC-1 fusion protein have been evaluated in phase I trials. T-cell responses to vaccine were seen and toxicity was minimal (260). This approach is currently being evaluated in a phase II/III trial with the product Cvac for patients with ovarian cancer in complete remission following first-line chemotherapy (NCT01521143). The trial is expected to enroll 1000 patients with a primary endpoint of progression-free survival. Secondary endpoints are overall survival, safety, and health related quality of life.

WHOLE TUMOR VACCINES

Several groups have used viruses to increase tumor cell immunogenicity for whole tumor cell vaccination. Objective responses have been seen after intracavitary delivery of a viral oncolysate vaccine generated with ovarian cancer cell lines infected with influenza-A virus (261,262) or with autologous tumor cells infected with Newcastle disease virus (263). A recent study

investigated preclinical use of replication-restricted herpes simplex virus (HSV) 1 to infect autologous tumor cells for vaccine preparation. HSV-infected tumor cells used directly or pulsed on dendritic cells elicited potent antitumor immune response in the mouse, which was superior to the use of UV-irradiated tumor cells (218,264,265). Thus, whole tumor antigen vaccines can produce objective response if immunogenicity is increased through the use of pathogens. An alternative approach to deliver effectively whole tumor antigen is by using dendritic cells (DCs). In a pilot study using mature DCs pulsed with whole autologous tumor lysate, 3 of 6 subjects demonstrated remission inversion, i.e., their progression-free survival postvaccination was longer than the interval between prevaccine recurrence and prior chemotherapy treatment (266).

Although whole tumor vaccines offer distinct advantages, some drawbacks warrant consideration. First, surgical procurement of large number of autologous tumor cells may not be possible in many patients. Alternatives to this limitation exist, including use of allogeneic cell lines or the use of tumor mRNA. RNA electroporation of DCs is a convenient approach to generate a potent tumor vaccine (218). An additional concern with whole tumor vaccination relates to the inclusion of a large number of “self” antigens, which could potentially drive tolerogenic responses, i.e., expand Treg rather than cytotoxic lymphocyte responses. Recent work has demonstrated that DCs can be polarized *ex vivo* with the use of interferons, Toll-like receptor agonists or p38 mitogen-activated protein kinase (MAPK) inhibitors to drive cytotoxic lymphocytes and Th17 effector cells at the expense of Treg activity (267). On the other hand, if immunization is successful, there may be increased concern for breaking tolerance to “self” antigens, leading to immunopathology. To date, pilot studies with whole tumor vaccines have reported no autoimmunity in patients with ovarian cancer.

A major limitation of cancer vaccines presently stems from the inability to elicit a rapid and overwhelming T-cell response, which is required to reject established tumors. A potential solution to this limitation is provided by combinations with immunomodulation therapy previously discussed aiming at breaking peripheral tolerance mechanisms, which may reduce the number of tumor reactive T cells required to reject tumors. For example, a recent study has shown that immunomodulation through blockade of the endothelin B receptor, a VEGF-regulated gene, markedly increases the efficacy of weak vaccines by reversing the inhibitory function of tumor endothelium and enabling homing of tumor-reactive T cells (268,269). Furthermore, depletion of Treg is a likewise critical maneuver to enhance vaccine therapy (107). A pilot study at the University of Pennsylvania is testing this hypothesis by administering partially mature DCs pulsed with autologous tumor cell lysate to subjects with recurrent ovarian cancer in combination with immunomodulation with oral metronomic cyclophosphamide (to deplete Treg) (270) and bevacizumab (to disrupt the blood-tumor endothelial barrier) (269). An additional approach to enhance the efficacy of vaccines may be provided by combination with postvaccine adoptive transfer of *ex vivo* expanded T cells.

ADOPTIVE CELLULAR THERAPY

Effective cancer immunotherapy is dependent on the presence of large numbers of antitumor lymphocytes with appropriate homing and effector functions that enable them to seek out and destroy cancer cells *in vivo*. The adoptive transfer of *ex vivo* expanded tumor-reactive T cells holds the potential of achieving this condition in a short period of time, as shown in Figure 15.3. Clinical trials testing spontaneous or induced polyclonal or oligoclonal T cells conducted in the past two decades have provided crucial lessons that can guide further optimization. The

use of *ex vivo* expanded TILs has yielded the best clinical immunotherapy results to date. The advantages of TIL-based adoptive therapy include the presence of spontaneously occurring T cells with natural avidity against tumor which have escaped thymic deletion; the use of a polyclonal population of T cells, which can limit immunologic escape of tumors; and the natural selection of patients whose tumor microenvironment is already conducive to T-cell homing. Initial studies using TILs in the treatment of metastatic melanoma during the late 1980s and early 1990s demonstrated objective antitumor responses, but they were short-lived. Based on animal studies showing that host lymphodepletion prior to T-cell transfer enhances persistence of T cells and antitumor response, a scheme of incremental lymphodepletion through high dose nonmyeloablating chemotherapy and added whole body radiation was tested. Infused cells were both long-lived, and highly penetrating, showing regression of voluminous metastatic tumors, with up to 16% complete response and 72% overall objective response rates in recent reports with maximal lymphodepletion and radiation. T cell persistence correlated with long lasting responses (103,202). Although these are phase I studies accruing a highly selected cohort of patients with metastatic melanoma with preexisting antitumor immunity, whose tumors yield tumor-reactive TILs, the results clearly demonstrate the power of adoptive immunotherapy and dispel the assumption that immunotherapy can only control small tumors (271). Interestingly, adoptive transfer of CD8⁺ clones expanded *ex vivo* to large numbers and transferred following lymphodepletion did not result in objective tumor response in melanoma, indicating that polyclonal T cells, a mixture of memory and effector cells, and CD4⁺ cells are necessary for tumor rejection (272).

Although TIL-based adoptive therapy has been mainly tested in melanoma, there is evidence that it is also an important opportunity in ovarian cancer. In the early 1990s, ovarian cancers were found to yield reactive TILs after IL-2 culturing *in vitro* that may be amenable to adoptive transfer (273,274). Moreover, pilot clinical trials of adjuvant therapy with adoptive transfer of tumor-derived lymphocytes expanded *ex vivo* with IL-2, following surgical debulking and frontline chemotherapy, showed a marked survival advantage (275,276). Stage III EOC patients treated with consolidation adoptive transfer of expanded TILs after completion of cisplatin-based frontline chemotherapy (n = 13) had 3-year overall survival rate of 100%, while that of a control group of patients (n = 10) receiving only chemotherapy was 67.5% ($p < 0.01$). The 3-year disease-free survival rate of the patients in the TIL group and in the control group was 82.1% and 54.5%, respectively. While these results can be limited by the lack of randomization, they nevertheless support the feasibility of adoptive therapy for ovarian cancer (275).

Optimization of adoptive TIL therapy is a matter of intense investigation and currently directed at: a) optimizing methods to select tumor-reactive TIL and expand them under optimal costimulation conditions that allow preferential expansion of specific T-cell phenotypes; and b) optimizing host and/or tumor conditioning. As shown in the melanoma trials, although infused cells had an effector phenotype (CD27⁻ CD28⁻ CD45RA⁺ CD62L⁻ CCR7⁻), TILs that persistent at two months in association with tumor regression were characterized by a less differentiated phenotype (CD27⁺ CD28⁺ CD45RA⁺ but CD62L⁻ CCR7⁻) and longer telomeres (277–281). These results argue that use of memory rather than effector cells may be more convenient for adoptive transfer (282), which has been confirmed by mouse models (283). Because TILs comprise a large number of tumor-reactive effector cells, identification of culture conditions that preferentially expand memory phenotypes is a priority. Recent technological advances with the development of artificial antigen-presenting cells (aAPCs) expressing a variable repertoire of costimulatory molecules and cytokines has generated new opportunities to provide the desired costimulatory molecules and cytokines

FIGURE 15.3. Cellular therapy.

to re-educate TILs, improving their potency and function *in vivo*. Carl June and colleagues recently described the development of a next generation K562-based aAPC platform capable of expressing multiple gene inserts, including human lymphocyte antigen (HLA)-A2, CD64 (the high-affinity Fc receptor) CD80, CD83, CD86, CD137L (4-1BBL) and CD252 (Ox40L), and a variety of T cell supporting cytokines (284). Cell-based aAPCs have proven to be more efficient at activating and expanding CD8⁺ CD28⁺ T cells, and antigen-specific T cells, than the magnetic bead-based aAPC (284). Importantly, TILs from ovarian cancer patients undergo robust expansion while maintaining their tumor reactivity after K562-based aAPC stimulation (Powell and colleagues, unpublished).

A proportion of patients are not eligible for TIL-adoptive therapy, because tumors are either unresectable or yield no tumor-reactive TILs. One strategy to overcome the daunting task of raising large numbers of tumor-reactive T cells is by engineering T cells to redirect their specificity. This can be accomplished by transducing lymphocytes to express a cloned T-cell receptor (TCR) with high affinity to tumor-associated epitopes. In this case, the cloned heterodimeric TCR is transduced to mixed peripheral blood T cells isolated from the patient, creating a large amount of bispecific T cells, which are polyclonal with respect to their original TCR, but potentially monoclonal for the cloned TCR (if recombination with endogenous TCR is minimized) (285). Alternatively, T cells can be transduced with a chimeric immunoreceptor (see below).

Recently, the clinical feasibility, safety, and preliminary efficacy of redirecting T cells of patients with melanoma using a TCR specific to MART-1, a melanoma antigen, was demonstrated (286). The genes encoding α and β chains of the TCR were cloned from a TIL clone derived from a patient demonstrating a near-complete regression of metastatic melanoma after adoptive cell transfer of TILs. Gene transfer resulted in transfection of 30% of CD8⁺ cells. Adoptive transfer of TCR-transduced cells in 15 patients resulted in durable engraftment at levels exceeding 10% of peripheral blood lymphocytes for at least 2 months after the infusion. High sustained levels of circulating, engineered cells at 1 year after infusion was observed in 2 patients who demonstrated objective regression of metastatic melanoma lesions (286). TCR-based engineering represents a potentially powerful strategy for ovarian cancer therapy as TCRs that recognize HLA-A2 restricted epitopes from known ovarian cancer antigens such as NY-ESO-1, p53, and others are available for clinically testing as well (287–290). Optimization through selection of naturally occurring or recombinant high affinity receptors, engineering to prevent recombination with endogenous TCR, and the use of lentiviral vectors developed in the June lab with transfection efficiency above 90% are poised to improve this approach significantly (291).

An alternative strategy to engineer T cells with redirected specificity is through genetic modification to recognize antigens in an MHC-unrestricted fashion through the use of chimeric immunoreceptors (CIR), fusion genes encoding an extracellular domain that specifically binds to tumor epitopes through a single chain

variable fragment (scFv) antibody, linked to intracellular signaling modules that mediate T cell activation (285,292,293). The tumor binding function of CIR is usually accomplished by the inclusion of a single chain variable fragment (scFv) antibody, containing the V_H and V_L chains joined by a peptide linker of about 15 residues in length. In principle, universal targeting vectors can be constructed, because the scFvs bind to native cell surface epitopes and bypass the requirement for MHC restriction (294,295). Thus, in comparison to TCRs, CIR have 2 major advantages: (a) their HLA-independent recognition of antigen, which makes them broadly applicable regardless of the subject's HLA and regardless of the level of HLA expression on tumor cells, and (b) their signaling, which redirects T-cell cytotoxicity and permits T-cell proliferation and survival upon repeat antigen exposure. A potential drawback stems from their potential immunogenicity, if scFv are nonhuman. This can be averted by using human scFv. CIR will then be the tools of choice for T-cell engineering for cancer immunotherapies.

A large number of CIRs targeting diverse tumors have been developed (reviewed elsewhere) (285,296), however, clinical pilot tests are just beginning. Some of the ovarian tumor antigens and CIR investigated *in vitro* and *in vivo* in T lymphocytes are FBP (297,298), MUC-1 (299), HER2 and mesothelin (300). There has been a single study of adoptive transfer of CIR T cells in ovarian cancer (301). While this study demonstrated safety, the results were disappointing, with no clinically evident tumor responses, most likely due to low expression of the transgenic CIR, and poor persistence of the transferred T cells (301). Persistence can be dramatically improved by using human scFv and by adding costimulatory signaling capabilities to the intracytoplasmic domain of CIRs. Indeed, one issue that needs to be addressed with CIRs is that signaling through the cytosolic domain of the usual scFv-TCR ζ single chain construct does not fully replicate the multichain TCR signaling complex (138,139). This is solved by incorporating additional signaling modules in the cytoplasmic domain of the chimeric receptor. Efficient lentiviral and tissue culture technology now enables highly efficient transduction of primary T cells (291).

CONCLUSIONS

Many patients with cervical, endometrial, or ovarian cancer, who will eventually develop treatment resistant disease, can initially be rendered free of clinically detectable disease by surgery, radiation therapy, and/or chemotherapy for varying periods. This setting where the targets are circulating tumor cells or micrometastasis rather than bulk disease is ideal for treatment with immune based interventions. Significant advances have been made in the field of cancer immunotherapy over the last decade. It has been equally important to identify tumor antigens with immunogenic potential, as well as the application of a variety of strategies to augment the antitumor response. Numerous nonrandomized phase II immune targeted trials have shown a correlation between overall survival and the presence of its respective effectors. However, these benefits have not been confirmed to date in phase III trials in gynecologic malignancies, showing the continued importance of objectively evaluating promising approaches in early phase studies.

The way forward is to proceed with discovery oriented translational research in the form of clinical trials that can quickly assess alternative vaccine strategies, immunological monitoring methods, and tumor escape mechanisms. The key to success will depend on the continued development of organized multidisciplinary groups with the adoption of standardized patient populations (for example, second or third remission), as well as standardized monitoring to enable the comparison of single vaccine variables such as the constitution of an antigen (protein, peptide, viral vectors, or DNA), the method, frequency, and intensity of antigen delivery, and the effect of different adjuvants. In concert, a combination of strategies with the aim of achieving an integrated response (antibody and T-cell effectors) along with immunomodulatory approaches seem most likely to have the potential of demonstrating a meaningful clinical benefit in the future.

16 Hormones and Human Malignancies

G. LARRY MAXWELL ■ MIAN M. K. SHAHZAD ■ LAUREL W. RICE

INTRODUCTION

Hormones have been linked to several of the most commonly occurring human malignancies, including breast, endometrium, ovary, and colon. The ability of hormones to stimulate cellular proliferation, leading to random genetic errors, is assumed to be the basis by which these peptides promote the development of human neoplasia. The pathways and mechanisms by which hormones affect their biologic responses is an exploding area of research, largely as a result of the tremendous potential for translational research and improved patient care. This chapter reviews the relationship between hormones and human malignancies, specifically as they relate to risk, prevention, and treatment.

HORMONE RECEPTOR PATHWAYS AND MECHANISMS

Steroid hormones perform critical functions in morphogenesis and normal physiology of female reproductive organs (1). These hormones are involved in many growth and developmental processes and exert their physiologic effects by binding to their particular receptors (2). Steroid hormone receptors are part of the ligand-activated nuclear transcription factor superfamily. The members of this superfamily also include glucocorticoid, mineralocorticoid, androgen, thyroid, retinoid, progesterone receptors (PR), and estrogen receptors (ER) (3). In the inactive state, these receptors are bound to repressor/chaperone complexes within the cytoplasm. Upon binding to their specific ligands, the receptor-ligand complex undergoes dimerization, which is followed by nuclear localization (leading to the name “nuclear receptor”). Inside the nucleus, the steroid hormone-receptor complex binds to specific DNA sequences called response elements. (4). Also participating in this interaction are nuclear receptor coactivators and corepressors, as well as the general transcription machinery (5). The net result of these interactions is the transcriptional activation or repression of hormone-responsive genes. More recently, nongenomic actions of ER and other nuclear receptors have been documented. These effects result from protein-protein interactions and membrane-associated nuclear receptor action (6).

Steroid Hormone Biosynthesis

While a comprehensive account of steroidogenesis is beyond the scope of this chapter, a succinct synopsis is presented (Fig. 16.1)

to underscore targets of therapeutic relevance. All steroid hormones are derived from cholesterol. In steroid biosynthesis, cytochrome P450-linked side-chain cleaving enzyme (P450 ssc) acutely regulates the rate-limiting step and converts cholesterol to pregnenolone (7). This naturally produced hormone in the body is sometimes referred to as the “mother hormone” and serves as a precursor for dehydroepiandrosterone (DHEA) and all steroid and sex hormones. Conversion of cholesterol to pregnenolone in the ovary is tightly regulated by follicle-stimulating hormone (FSH) and luteinizing hormone (LH) via cAMP and protein kinase A (PKA) signaling (8). This leads to increased production of androgen intermediates, androstenedione and testosterone, that are then converted by the P450-aromatase enzyme to estrone and estradiol (E2), respectively. P450-aromatase is not exclusively expressed in ovarian tissues. Interestingly, its expression in many other tissues results in biosynthesis of local E2 (9). The availability of locally produced E2 may be particularly important in both men and postmenopausal women, where ovarian hormone production is lacking. High levels of locally synthesized and readily available E2 have also been implicated in breast carcinogenesis (10).

Recently, Ghosh et al. have solved the crystal structure of CYP19A1 and revealed a small active cleft that is well suited to bind androstenedione snugly, prior to its conversion to estrone (11). Data also indicate that CYP19A1 has wide tissue distribution (including placenta, ovary, testes, and adipose tissue), and its expression has been demonstrated to be associated with about 75% of estrogen-dependent breast cancers (12). Aromatase inhibitors in this specific patient population have resulted in a substantial reduction in the risk of breast cancer recurrence (13). Although other risks emerge, including grade 3 and 4 cardiovascular events and bone fractures (14,15). Additionally, we now know that several tissue types have tissue-specific expression of the CYP19A1 gene promoter, and the presence of tissue-specific promoters has raised the possibility of developing more selective aromatase inhibitors. Such agents would be able to, for instance, block E2 in breast cancer, without affecting estrogenic pathways in bones (16,17).

Steroid Hormone Receptor Structure

Steroid receptors are comprised of six functional domains (Fig. 16.2) (18). The A/B domain is highly variable among the different members of this family and contains within it the hormone-independent activating 1, or AF-1, domain. The relatively conserved C region contains the DNA-binding domain (DBD). Within the central DBD, two zinc fingers target the receptors to their corresponding hormone response elements. The DBD binds as a dimer, with each monomer recognizing half of the palindromic DNA sequence of the response element. The D domain

FIGURE 16.1. Molecular biology of steroid hormone synthesis. Notice the important role of aromatase in the conversion of androgens to estradiols.

is a peptide linker that connects the DBD to the ligand-binding domain (LBD). The E region is a multifunctional domain and contains amino acids involved in ligand binding, receptor dimerization, nuclear localization, coactivator/corepressor interaction, and ligand-dependent activating function (AF-2). The F region is a variable extension of the E region.

Estrogen Receptors

The ER mainly functions as a ligand-regulated, DNA-binding transcription factor, resulting in modulation of gene expression of proteins involved in key pathways related to cancer progression. However, additional ER functions, independent of DNA binding, have also been reported (19,20). ERs can be recruited to the DNA by indirect tethering through other DNA-bound transcription factors, including members of the activating protein-1 (AP-1) transcription family (4,21,22). Due to alternative RNA splicing, several isoforms of the ER are known to exist, but ER- α and ER- β are considered to be the main isoforms. We now know that ER- α is encoded by the *ESR1* gene

and ER- β is encoded by the *ESR2* gene. The *ESR1* and *ESR2* genes are located on the 6th and 14th chromosomes (6q25.1 and 14q23), respectively (23).

In humans, the ERs exhibit 96% and 58% homology in their DBD and LBD, respectively. These structural differences in ERs lead to discrete ligand affinities and physiological properties. For example, estrone and raloxifene bind preferentially to ER- α , while estriol and genistein have higher binding affinity for ER- β . Furthermore, tamoxifen and raloxifene exhibit partial agonist activities after binding to ER- α , while they act as pure antagonists when bound to ER- β (24). This is thought to result from distinct conformational changes induced by ligand binding in the two receptors (25).

Both ERs are widely expressed in many tissue types; however, there are important differences in the pattern of their expression. ER- α is the predominant ER isoform in many tissues, including breast cancer, endometrium, ovarian stroma, and the hypothalamus. ER- β has notably higher expression in ovarian granulosa cells, prostate gland, gastrointestinal tract, endothelial cells, heart, lung, kidney, brain, and bone (26–28). However, some expression of both receptors is observed in

FIGURE 16.2. Functional domains of the human estrogen receptor: The A/B domain is highly variable among the different members of this family and contains the hormone-independent activating 1, or AF-1, domain. The C region consists of the DNA-binding domain (DBD). The D domain is a peptide linker that connects the DBD to the ligand-binding domain (LBD). The E region is a multifunctional domain and contains the LBD as well as amino acids involved in receptor dimerization, nuclear localization, coactivator/corepressor interaction, and ligand-dependent activating function (AF-2). The F region is a variable extension of the E region.

many tissues. Data now indicate a correlation between ER- β transcript levels and expression of oncogenes in cancer cells and also suggest a role of ER- β in endometrial carcinogenesis (29). As noted above, ER- α and ER- β have been shown to have unique physiologic properties. In addition, they are capable of forming ER- α (aa) or ER- β (bb) homodimers or (ER- α /ER- β) heterodimers, thus influencing each other's function (30). In this context, ER- β has been shown to function as a dominant inhibitor of ER- α (21). Therefore, it is likely that normal physiologic function in E2 responsive tissues relies on the relative expression ratio of ER- α and ER- β in those tissues. Recently, Iyer and colleagues have shown that estrogen promotes ER-negative breast tumor growth by recruitment of pro-angiogenic bone marrow-derived myeloid cells in murine xenograft models, and the researchers demonstrated that ER- α expression is present only in bone marrow-derived cells and this expression was required and sufficient to promote breast tumor growth when challenged with estrogen (31).

Accumulating evidence suggests that changes in normal ER- α -to-ER- β ratio may be associated with neoplastic states. Cancers of the ovary, colon, and endometrium are all characterized by a relative loss of the normally predominant ER subtype when compared with normal tissue (32–36). Whether these changes predispose to or are a result of carcinogenesis remains to be elucidated. The development of ER- α , ER- β , and double knockout mice (ERKO, β ERKO, and $\alpha\beta$ ERKO, respectively) has helped with the identification of each receptor's physiologic role in its target organs (37). These findings are summarized in Table 16.1. Recently, genotyping data from more than 12,000 BRCA1 and 7,000 BRCA2 mutation carriers compiled from 40 studies identified ER-related SNP (rs67397200) at chromosome 19p13.1 that portends an increased risk of ovarian cancer for BRCA1 (HR 1.16) and BRCA2 (HR 1.30) mutation carriers. Identification of this cancer susceptibility locus may also be useful for ovarian cancer risk prediction for BRCA1 and BRCA2 mutation carriers (38).

Several of the ER- α and ER- β “splice variants” have been demonstrated to possess altered hormone binding and/or transcriptional properties. Some can act in a dominant negative fashion by dimerizing with the wild-type receptors and interfering with their function *in vitro* (39). As mentioned above, ER has been shown to regulate transcription by interacting with other transcription factors and signal mediators (40–42). This mechanism involves protein-protein interaction and does not require DNA binding. An example of this type of interaction is the influence of ERs on the transcriptional activity mediated by the components of the AP-1 pathway such as jun and fos (34). In the presence of ER- α , E2 stimulates AP-1-dependent transcription, while tamoxifen and raloxifene inhibit it. In contrast, ER- β produces the opposite effect, with estradiol inhibiting and tamoxifen and raloxifene stimulating AP-1-mediated transcription. The activation of ER- α also results in induction

of fos-related antigen 1 (fra-1) and regulates uterine stromal differentiation and remodeling during early pregnancy (43). An additional mechanism of ER action involves “cross-talk” with growth factors including insulin-like growth factor 1 (IGF-1), epidermal growth factor (EGF), and transforming growth factor β (TGF- β) (44,45). EGF can mimic the effects of E2 on the reproductive tract. This effect is dependent on ER- α because it can be blocked by ER antagonists and is absent in ERKO mice, despite an intact EGF signaling cascade (46). Mechanisms for this cross-talk involve signal transduction from growth factor receptors via the ras/raf/MAPK, as well as the AKT/PI3K cascade intermediaries culminating in the phosphorylation and activation of ER's AF-1 domain (47). AKT activation results in cell survival and inhibition of apoptosis. In normal tissue, this pathway is kept in check by a phosphatase called PTEN. PTEN is a tumor suppressor that negatively regulates the PI3K/AKT pathway by dephosphorylating PIP3. The activation of the PI3K/AKT pathway is particularly relevant in endometrial adenocarcinoma, where up to 80% of malignancies and 55% of premalignant lesions have been shown to harbor PTEN mutations (48,49). Most investigations of the growth factor–ER cross-talk have involved ER- α . However, positive regulation of AKT over ER- β was recently reported via phosphorylation of glucocorticoid receptor-interacting protein 1 (GRIP1) transcriptional coactivator (50).

For decades it has been observed that exposure to estrogens can lead to immediate physiologic sequelae independent of transcriptional effects. These observations supported the presence of ERs outside the nucleus as the mediators of these nongenomic steroid hormone effects (4,51). The nongenomic effects of estrogens appear to follow at least two major pathways. The interactions of ER- α and its splice variants with components of the growth factor signaling cascades including MAPK and PI3K pathways are important (52,53). Recently, *in vitro* and *in vivo* data indicate that estrogen promotes ovarian cancer growth both directly and indirectly, by making the tumor microenvironment more conducive to tumor growth (54). Here it is essential to recognize that cellular exposure to estrogen results in a multitude of functions that can be measured with distinct kinetics. Specifically, the rapid events that take place within minutes are termed pre-genomic and utilize the second messenger pathway. The pre-genomic events may also ultimately lead to changes in gene transcription, as do the delayed events (55). This mechanism involves a G-protein coupled receptor, GPR30, an intracellular transmembrane receptor that localizes mainly to the endoplasmic reticulum. In this pathway, estrogens diffuse through the plasma membrane and bind GPR30 at the endoplasmic reticulum. This results in intracellular calcium mobilization and synthesis of phosphatidylinositol 3,4,5-trisphosphate in the nucleus. Activation of this pathway has been demonstrated in cells that lack ER- α and ER- β expression (56).

Table 16.1 Summary of Findings from Estrogen Receptor Knockout Mice Experiments

Organ	Phenotype		
	ERKO	β ERKO	$\alpha\beta$ ERKO
Pituitary gland	High LH	None	High LH
Ovary	Hemorrhagic cysts, high estrogen and testosterone due to high LH, anovulatory	Reduced ovulation	Anovulatory, “sex-reversed” follicles with Sertoli-like cells
Endometrium	Estrogen insensitive, no growth or induction of estrogen-responsive genes	Normal growth and response to estrogen	Estrogen insensitive, no growth or induction of estrogen-responsive genes
Breast	No pubertal development	Normal development and lactation	No pubertal development

Abbreviation: LH, luteinizing hormone.

Progesterone Receptors

The progesterone receptor (PR) is an intracellular steroid receptor that belongs to the nuclear receptor subfamily of receptors (i.e., NR3C3) (57). These nuclear hormone receptors, in general, are involved in diverse physiological functions, including differentiation, embryonic development, and cellular homeostasis. However, dysregulation of nuclear receptor superfamily members has been implicated in many disease states, including cancer (58). Multiple mechanisms through which PR mediates gene expression are regulated by numerous cellular processes that originate either within the cell or in the extracellular environment (59). The effects of progesterone are mediated by two PR proteins, PRA and PRB. In humans, the two PR proteins are encoded by the gene, *PGR*, which is located on chromosome 11q22 (60). These 2 receptors differ due to the additional 164 amino acids present in the N-terminus of PRB. Both PRA and PRB contain transcription-activating functional (AF) domains: AF-1 and AF-2. The N-terminal region of PRB contains an additional AF domain (AF-3) (61). The two PRs exhibit differences in function that are cell context and promoter dependent. For example, PRB uniformly exhibits progestin-dependent transactivation in the various cell types examined. However, PRA's transcriptional activity is cell and response-element specific. When tested on simple progestin response elements (PRE), PRA and PRB display similar transactivational activity. However, PRA's activity is reduced or eliminated on more complex response elements (62). In addition, PRA has been shown to act in a dominant negative fashion, antagonizing the transcriptional activity of not only PRB, but also other nuclear receptors such as the glucocorticoid, mineralocorticoid, androgen, and estrogen receptors (63).

In general, most tissues express equal levels of the two PR isoforms. However, differential expression can be observed, as each promoter is regulated independently. For example, in the endometrium, stromal cells express predominantly PRA throughout the menstrual cycle, whereas the epithelial cells switch from PRA to PRB during the early secretory phase (64). PRA knockout mice (PRAKO) exhibit endometrial hyperplasia mediated by PRB following exposure to progestins (65). Similar studies using PRB knockout mice (PRBKO) have shown that PRA is sufficient for eliciting progesterone's reproductive responses in the ovary and the uterus. In contrast, PRB is required to elicit normal proliferative responses of the mammary gland to progesterone (66). Finally, changes in PR isoform relative or overall expression have been described in endometrial, ovarian, and breast cancers (30,46,67).

It is generally thought that the expression of PR in ovarian cancer may be protective (68,69). Recent data indicate that PRB activation by other second messengers (e.g., cAMP) results in cell cycle arrest, induction of cellular senescence, and suppression of oncogenicity of ovarian cancer (70). A decrease in *PGR* content due to loss of heterozygosity and/or polymorphisms of *PGR* are associated with increased risk of ovarian cancer, and signifies that activation of *PGR* may guard against the development of ovarian cancer (71–73). Preclinical data now indicate that certain microRNAs may also regulate the expression of *PGR*, and targeting of *PGR* by specific microRNAs is seen in transition from normal to endometrial cancer states (74). Additional evidence supports that progesterone may also signal through other receptors that may be localized to the membrane (75). For example, Peluso and colleagues, using orthotopic ovarian cancer mouse models, recently demonstrated that progesterone membrane component-1 regulates the development and sensitivity to cisplatin in ovarian cancer (76).

Nongenomic functions of *PGR* involve the extranuclear *PGR*s that associate through proline-rich domain to interact with SH3 domain of Src kinase. This complex cascade involves activation of the EGFR/c-Src/Ras/ERK pathway and the PI3K/AKT pathway, resulting in a pro-tumorigenic role in cancer cell

biology (77,78,79). More recently, progesterone was shown to mediate mammary gland stem cell self-renewal (80). Knowing that *PGR* function is altered by the action of protein kinases and that activation of *PGR* can lead to the activation of several kinases known to enhance tumor progression (81), it is essential to understand these critical molecular interactions in depth to significantly improve our approaches for prevention and treatment of human malignancy.

HORMONES AS RISK FACTORS FOR HUMAN MALIGNANCIES

Exogenous Hormones and Modulation of Cancer Risk

Breast

Hormone Replacement Therapy

Women without history of breast cancer. Multiple epidemiologic investigations have evaluated the relationship between hormone replacement therapy (HRT) and breast cancer. In a meta-analysis of 51 studies of 52,705 women with breast cancer and 108,411 women without breast cancer, the Collaborative Group on Hormonal Factors in Breast Cancer (CGHFBC) determined that the risk of developing breast cancer is increased in women using HRT. The risk increases especially among women with >5 years of use (relative risk [RR], 1.3; 95% confidence interval [CI], 1.21–1.49). The cumulative incidence of breast cancer was 45 per 1,000 women between the ages of 50 and 70 years, and use of HRT for >5 years was associated with an estimated cumulative excess of 2 breast cancers for every 1,000 users. The increased risk of breast cancer associated with prolonged HRT was greater for women with low weight or low Body Mass Index (BMI). Breast cancers diagnosed in women who had a history of HRT was inclined to be less advanced clinically compared with women with a negative history of HRT use (82). The Breast Cancer Detection Demonstration Project, a cohort study with 46,355 postmenopausal women, 2,082 of whom were diagnosed with incident cases of breast cancer, reported that women who had taken unopposed E2 had a 1.2-fold (95% CI, 1.0–1.4) increase in breast cancer risk, while women taking combination E2 and progestin regimens had a 1.4-fold (95% CI, 1.1–1.8) increased risk. Breast cancer risk was significantly elevated only in recent users with a BMI less than 24 (83). Finally, a recently reported case-control study involving 1,897 women with breast cancer revealed that women using combination HRT had a statistically higher risk of breast cancer (odds ratio [OR], 1.24; 95% CI, 1.07–1.45) than women taking unopposed E2 (OR, 1.06; 95% CI, 0.97–1.15) (84).

The Women's Health Initiative (WHI), a randomized, double-blind, placebo-controlled trial, recently reported the interim analysis of 8,506 women who received continuous combination HRT (0.625 mg of conjugated equine estrogen [CEE] plus 2.5 mg of medroxyprogesterone acetate [MPA]) versus 8,102 women prescribed placebo. The Data and Safety Monitoring Board for the trial recommended early cessation of this trial arm secondary to the observed adverse effects. Interim results from the WHI study revealed that the risk of coronary heart disease (hazard ratio [HR], 1.29; 95% CI, 1.02–1.63), stroke (HR, 1.41; 95% CI, 1.07–1.85), and pulmonary embolism (HR, 2.13; 95% CI, 1.39–3.25) were all significantly elevated in patients receiving continuous combination HRT. The observed increased risk of breast cancer (HR, 1.26; 95% CI, 1.0–1.59) was similar to results from the aforementioned observational studies (85). A more detailed evaluation of the WHI data used a weighted Cox proportion hazards analysis in an effort to account for the lag in time required to achieve the full effects of the hormone on breast

cancer incidence. In this analysis, the rate of invasive breast cancer was increased in patients receiving progestin plus estrogen (HR, 1.24, weighted $p < 0.003$) (86). Extended follow-up of the patients from the WHI intervention trial was continued among 8,052 surviving participants (95%) in a post-intervention study for a mean of 8 years. More breast cancers were diagnosed among women receiving CEE plus MPA versus placebo (HR, = 1.27; 95% CI, 1.06–1.51) (87). Estrogen plus MPA had a greater influence on breast cancer incidence than placebo if initiated closer to menopause (88). The breast cancer developing in patients receiving the hormonal regimen was also not restricted to hormone receptor–positive tumors (89).

Further analysis has revealed that breast cancer diagnosed in women receiving CEE plus MPA, when compared with placebo patients diagnosed with breast cancer, were more likely to have metastatic node involvement, even though between the two groups the tumors were similar in terms of grade and histology (88). The combination of CEE plus MPA compared with placebo has been shown to interfere with mammographic detection, potentially leading to breast cancers being diagnosed at a later stage of disease (90). Moreover, a 11-year follow-up analysis recently has shown that breast cancer mortality has increased among women who received CEE plus MPA compared with placebo (88). Since the original results from the WHI were released in 2002, there has been a decrease in the nationwide use of postmenopausal hormone therapy (91). In addition, patients on HRT were diagnosed with larger tumors at a more advanced stage, compared with patients who received placebo (88).

In the WHI trial, 10,739 postmenopausal women with prior hysterectomy received 0.625 mg of CEE ($n = 5,310$) versus placebo ($n = 5,429$). In the initial manuscript, the WHI investigators reported that there was a possible reduction in breast cancer incidence, but the results were not statistically significant (HR, 0.77; 95% CI, 0.59–1.01) (92). Further analysis of the data revealed that treatment with CEE for 7 years does not appear to increase the incidence of breast cancer (77). Extended follow-up of the patients from the WHI intervention trial was continued among 7,645 surviving participants (78%) in a post-intervention study for a mean of 10 years. Analysis of intervention and post-intervention data revealed a lower incidence of breast cancer among patients receiving CEE (HR, 0.77; 95% CI, 0.62–0.95) (93).

Women with a history of breast cancer. Physicians are apprehensive about prescribing HRT to women with a positive personal history of breast cancer. The theoretical concern has been that exogenous hormones may stimulate the growth of dormant microscopic disease and ultimately lead to a decreased disease-free interval and survival.

Several case-control studies have reported that the rates of breast cancer recurrence among survivors taking HRT vary from 3% to 7% (94,80) and do not appear to significantly diverge from stage-specific population rates of recurrence. In a case control study by DiSaia et al. (81), 41 sporadic breast cancer patients taking HRT were matched to controls according to age, stage, and socioeconomic status. A majority of the patients had early-stage disease. Recurrences were detected in 12 patients with stage I disease, 1 with stage II, and 2 with stage III. No evidence of increased disease recurrence was noted among the patients receiving HRT. In a subsequent analysis by the same authors, 125 sporadic breast cancer survivors receiving HRT were compared with 363 control subjects matched according to age at diagnosis, stage of breast cancer, and year of diagnosis. The analysis revealed that the risk of death was lower among the breast cancer patients receiving HRT (OR, 0.28; 95% CI, 0.11–0.71). According to the American College of Obstetricians and Gynecologists, the projected absolute lifetime risk for non-HRT users is approximately 10 cases of breast cancer per 100 women. This risk would increase to 12 cases per 100 women using unopposed E2 and 14 cases per 100 women using

combined E2 and progestin (95). Data from a prospective, randomized trial is not available to answer this question.

Oral Contraceptives

Since their introduction in the 1960s, oral contraceptives (OCs) have been taken by over 200 million women throughout the world. The CGHFBC performed a meta-analysis of 54 epidemiologic studies on 53,297 women with breast cancer and 100,239 women without breast cancer. Women who were current users or had used OCs in the previous 10 years were at an increased risk of breast cancer (RR, 1.24; 95% CI, 1.15–1.33). Among women taking OCs, the breast cancers that developed were less advanced than those diagnosed in women with no history of OCP use (96). Because the results from this meta-analysis reflected data from studies completed over the prior 25 years, the Women's Contraceptive and Reproductive Experiences (Women's CARE) study was initiated in an effort to provide a more contemporary analysis of the relationship between OCs and breast cancer risk (97). In this case-control study, a total of 4,574 women with breast cancer and 4,682 controls were compared. The RR was 1.0 (95% CI, 0.8–1.3) for current OCP use and 0.9 (95% CI, 0.8–1.0) for previous use, suggesting that among women aged 35 to 64 years, current or former OCP use is not associated with a significantly increased risk of breast cancer.

Women with BRCA mutations. In the meta-analysis by the CGHFBC, the increased risk of breast cancer associated with OCP use was not influenced by a family history of breast cancer (96). However, a threefold increased risk of breast cancer was observed among women taking OCs who had a positive family history of breast cancer. This increased risk was observed only in women using high potency estrogen formulations before 1975 (98). A subsequent matched case-control study by Narod et al. revealed that among *BRCA1* carriers, an increased risk of early-onset breast cancer was evident in women who used OCs prior to 1975 (OR, 1.42; 95% CI, 1.17–1.75), used OCs prior to age 30 (OR, 1.29; 95% CI, 1.09–1.52), or who used OCs for 5 or more years. Despite the increased risk associated with OCP usage among *BRCA1* carriers, an increased risk of breast cancer was not observed among women with a *BRCA2* carrier status (99). In *BRCA1* carriers, the protective effects of OCs against ovarian cancer must be weighed against the possible increased risk of OCP use and breast cancer.

Ovary

Hormone Replacement Therapy

Women without a history of ovarian cancer. Recently, several well-designed case-control and cohort studies have evaluated the relationship between HRT and ovarian carcinoma. The American Cancer Society's Cancer Prevention Study II found that after accounting for OCP use and parity, postmenopausal women using HRT had higher rates of ovarian cancer-related deaths compared with nonusers (RR, 1.51; 95% CI, 1.16–1.96). The increased mortality risk was most notable for women using HRT for 10 or more years and persisted for up to 29 years after HRT cessation (100). This study is limited by the lack of information regarding estrogen and progestin potency. Another cohort study of 44,241 former participants in the Breast Cancer Detection Demonstration Project identified 329 women who developed ovarian cancer during follow-up. Multivariate analysis revealed an increased association of estrogen-only HRT with ovarian cancer (RR, 1.6; 95% CI, 1.2–2.0) after accounting for age, menopause type, and OCP use (101). In contrast, an increased risk of ovarian cancer was not noted among women who used estrogen and progestin. A Swedish case-controlled trial evaluated 655 case subjects with ovarian cancer and 3,819 control subjects. An

increased risk of ovarian cancer was noted among women with a history of either estrogen (OR, 1.43; 95% CI, 1.02–2.00) or estrogen with sequentially added progestins (OR 1.54; 95% CI, 1.15–2.05), particularly with hormone use exceeding 10 years. However, use of estrogen with continuously added progestin was not associated with an increased risk of ovarian cancer when compared with nonuse (102). The latter 2 studies suggest that HRT regimens containing both E2 and progestin may not have the increased risk of ovarian cancer observed with E2 therapy alone. However, the WHI recently identified, in women taking continuous combined HRT, an HR of 1.58 (95% CI, 0.77–3.24) for developing invasive ovarian carcinoma (103). The importance of the presence or absence of progesterone in HRT, as well as the type and potency, remains to be elucidated.

Women with a history of ovarian cancer. Only one randomized, controlled clinical trial exists evaluating the risk of ovarian cancer recurrence in patients receiving HRT. This study was designed to detect a 20% difference in survival between the two treatment groups. In this study, 130 patients less than 59 years of age with invasive ovarian cancer were randomized to continuous E2 HRT or no supplementation. The median disease-free interval for women receiving HRT versus those not receiving HRT was 34 months and 27 months, respectively, not reaching statistical significance (104). Multiple epidemiologic studies have revealed that OCPs are not a risk factor for ovarian cancer, but rather a means of prevention. See below.

Endometrium

Hormone Replacement Therapy

Women without a history of endometrial cancer. Multiple case-control and cohort studies also have suggested that the risk of endometrial cancer is elevated among patients receiving unopposed estrogen. A meta-analysis of 30 studies indicated that the summary RR of endometrial cancer was 2.7 for patients receiving unopposed estrogen (105). The use of unopposed estrogen has also been shown to be associated with the development of endometrial hyperplasia. In the Postmenopausal E2/Progestin Intervention (PEPI) trial, 875 patients were randomized to receive one of five regimens: (a) placebo; (b) CEE, 0.625 mg/day; (c) CEE, 0.625 mg/day plus continuous MPA, 2.5 mg/day; (d) CEE, 0.625 mg/day plus MPA, 10 mg for 12 days each month; or (e) CEE, 0.625 mg/day plus micronized progesterone (MP), 200 mg/day for 12 days per month. Patients receiving unopposed estrogen had a significantly increased risk of atypical adenomatous endometrial hyperplasia (34% vs. 1%) (106).

The addition of progestin to HRT has been shown to eliminate the increased risk of hyperplasia associated with unopposed E2. Although progestins have been associated with the effective treatment of endometrial hyperplasia, the data supporting the protective effects of progestins in HRT are limited. Many of the initial HRT regimens combining progestin and estrogens utilized the progestin for 7 days a month (107). Subsequent studies have recommended prolongation of the progestin component to at least 10 days each month. A case-control study of 832 endometrial cancer patients and 1,114 controls in Washington State revealed that patients using a regimen of estrogen combined with progestin (0.625 mg/day CEE, 2.5 mg/day MPA) had a significantly lower RR (RR, 1.4; 95% CI, 1.0–1.9) of endometrial cancer compared with patients who had taken unopposed estrogen (RR, 4.0; 95% CI, 3.2–5.1). However, patients receiving less than 10 days of cyclic progestin had an RR that was much higher (RR, 3.1; 95% CI, 1.7–5.7) than patients receiving 10 to 21 days of cyclic progestin (RR, 1.3; 95% CI, 0.8–2.2). Patients using either regimen of cyclic combination HRT had an increased risk of endometrial cancer when these regimens were taken for a duration exceeding 5 years (cyclic progestin <10 days per month: RR 3.7; 95% CI, 1.7–8.2; cyclic progestin

10 to 21 days each month: RR, 2.5; 95% CI, 1.1–5.5) (108). Subsequent data from the same investigators suggested that use of a continuous progestin HRT regimen may actually be protective against endometrial cancer (109). The largest case-control study of continuous HRT involved 79 case subjects and 88 control subjects, and it revealed that the RR of patients receiving continuous HRT was 1.07 (95% CI, 0.80–1.43) (92). Data from the WHI indicated that the HR for endometrioid endometrial cancer (EEC) was 0.81 (95% CI, 0.48–1.36) in patients receiving continuous HRT with average follow-up of 5.6 years (103). Extended follow-up of the patients from the WHI intervention and post-intervention trials over 8 years revealed that the incidence of endometrial cancer was still decreased among patients receiving CEE plus MPA compared with placebo, but this observation was not statistically significant (HR, 0.78, 0.52–1.16) (87).

There has recently been some suggestion that the degree of endometrial cancer risk reduction may be dependent on the type of progestin used in the continuous HRT regimen. A Swedish case-control study found that patients with a continuous HRT involving testosterone-derived progestins (i.e., norethisterone, norethisterone acetate, levonorgestrel, lynestrenol) were associated with a lower RR of endometrial cancer than those patients whose regimens involved progesterone-derived progestins (i.e., medroxyprogesterone) (110). Data from the Continuous Hormones as Replacement Therapy (CHART) study found no evidence of endometrial hyperplasia in participants who received norethindrone acetate (a testosterone-derived progestin). In this clinical trial, 1,265 patients were randomized to placebo versus one of eight treatment groups involving either various doses of unopposed ethinyl estradiol or various combinations of ethinyl estradiol plus norethindrone. A total of 1,134 endometrial biopsies were performed over a 2-year follow-up period among women who received the combination HRT regimen; 1,232 biopsies were performed in the women given unopposed E2. As the dose of unopposed ethinyl estradiol was increased, there were increased percentages of subjects with endometrial hyperplasia. There were no cases of hyperplasia noted among the subjects who received different doses of the testosterone-derived progestin norethindrone. The protective effect was noted even among patients randomized to receive doses of norethindrone as low as 0.2 mg (106). In contrast, the PEPI trial identified hyperplasia by a surveillance endometrial biopsy in 3 of 339 patients who received E2 with a progesterone-derived progestin. Further studies are needed to determine the degree of endometrial cancer risk influenced by the progestational activity of the progestin.

Women with a history of endometrial cancer. The use of E2 among patients with endometrial cancer is controversial. *In vitro* treatment of Ishikawa endometrial cancer cells with estrogen upregulates ER expression and augments growth in endometrial cancer cells (111,112). However, *in vivo* growth of residual microscopic endometrial cancer in patients has not been proven to date. Four retrospective cohort studies have evaluated patients with early-stage endometrial cancer receiving E2 postoperatively. Creasman et al. evaluated 221 patients with stage I disease, of whom 47 received postoperative HRT and 174 did not (113). Patients receiving HRT were followed for a median of 26 months. Regression analysis revealed that there was no increased risk of recurrent disease associated with HRT use, even when adjusting for age, tumor grade, myometrial lymph node status, and peritoneal cytology. A subsequent study by Lee et al. (114) compared the outcomes of 44 low-risk endometrial cancer patients (stage IA/IB G1/G2 disease) who received HRT following treatment, with 62 patients who received no HRT. There were no recurrences observed among the endometrial cancer patients receiving HRT for a median duration of 64 months. Investigators from the University of California, Irvine, have also failed to demonstrate an increased risk of recurrent disease associated with postoperative HRT (115).

In the first study, investigators evaluated 123 women with surgical stage I and II endometrial cancer. Sixty-one women received postoperative estrogen, and the mean duration of follow-up was 40 months. The disease-free interval was not significantly shortened among the patients receiving E2 (116). The second study was a retrospective cohort study that involved 75 patients with stage I–III disease who received HRT (51% E2 only, 49% E2 with added progestin) postoperatively. This group of patients was then matched according to decade of age at diagnosis and stage of disease to a group of endometrial cancer patients in the study cohort not receiving HRT. Both groups were comparable in terms of parity, tumor grade, depth of myometrial invasion, histology, lymph node status, surgical treatment, concurrent morbidities, and postoperative radiation. The patients receiving HRT were followed for a mean interval of 83 months, and the patients not receiving HRT were followed for a comparable interval of 69 months. Patients using HRT had a longer disease-free interval compared with nonusers of hormones. Among the 150 patients, only 8 patients had stage III disease (115).

In a Committee Opinion by the American College of Obstetricians and Gynecologists Committee of Gynecologic Practice, the members announced that “the decision to use HRT in these women (endometrial cancer patients) should be individualized on the basis of potential benefit and risk to the patient” (117). The Gynecologic Oncology Group (GOG) initiated a multicenter randomized, controlled trial aimed at an enrollment of 2,100 patients with stage I and II endometrial cancer. The study was closed after enrollment of 1,200 patients, because the majority of the patients were low-risk with stage IA and G1 disease. In the absence of adequate enrollment of more intermediate-to-high risk early-stage endometrial cancer patients, the number of recurrences used in the ad hoc sample-size determination would be underestimated, leading to suboptimal power for the clinical trial. With the closure of this GOG protocol, the safety of exogenous estrogen use in women who have undergone surgical management of endometrial cancer may never be fully ascertained.

Oral Contraceptives

Multiple epidemiologic studies have revealed that OCPs are not a risk factor for endometrial cancer, but rather a means of prevention (see below).

Selective Estrogen Receptor Modulators

The antiestrogen tamoxifen has been used in the adjuvant therapy of advanced breast cancer for years, and it has recently been evaluated as a chemopreventive agent in patients at a high risk for developing this malignancy. Tamoxifen increases the risk of second primary malignancies at other sites. A randomized, controlled trial involving 2,729 women performed by the Stockholm Breast Cancer Study Group revealed that patients given tamoxifen (40 mg/day) had a nearly sixfold increased risk of endometrial cancer, and a threefold increased risk of gastrointestinal cancer (118,119). These findings were confirmed in the National Surgical Adjuvant Breast and Bowel Project (NSABP). In this study, 2,843 patients with node-negative invasive breast cancer were randomized to receive tamoxifen (40 mg/day) or placebo. The RR of endometrial cancer in patients receiving tamoxifen was 7.5 (95% CI, 1.7–32.7) (120), compared with placebo (118). When the population-based rates of endometrial cancer from another NSABP trial (B-06), and data from the Surveillance, Epidemiology, and End Results (SEER) program were used in the calculation of risk, the RRs of endometrial cancer associated with tamoxifen use were 2.3 and 2.2, respectively. In addition, the average annual HR during follow-up was only 1.6 out of 1,000 in the group receiving tamoxifen (118,120), suggesting that routine screening would not be cost-effective.

Other selective estrogen receptor modulators (SERMs) are being evaluated as adjuvant treatment for breast cancer in an

attempt to avoid the increased risk of secondary malignancies, while maintaining the same or greater effectiveness. Results from the Multiple Outcomes of Raloxifene Evaluation (MORE) study indicate that patients receiving raloxifene had a lower incidence of breast cancer without any increase in endometrial cancer risk (118,121). However, the primary endpoint in this investigation was risk reduction of fracture in postmenopausal women with osteoporosis. In the National Surgical Adjuvant Breast and Bowel Project Study of Tamoxifen and Raloxifene (STAR) P-2 trial, investigators found that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer. Although the overall risk of developing endometrial cancer was similar in patients on raloxifene versus tamoxifen (RR, 0.62; 95% CI, 0.35–1.08), the incidence of hyperplasia was lower in the raloxifene group (RR, 0.16; 95% CI, 0.09–0.29) (122). Several other SERMs are under investigation. The results of ongoing clinical trials will confirm these preliminary findings and establish the applicability of this contemporary generation of SERMs.

Colon

Hormone Replacement Therapy

Multiple epidemiologic studies have revealed that HRT is not a risk factor for *colon* cancer, but rather protects against this malignancy (see below). The WHI randomized controlled trial revealed that colorectal cancer was reduced among patients who received CEE plus MPA (123). But the interpretation was obscured by a later stage at diagnosis. In the trial involving patients with a history of hysterectomy, patients receiving CEE compared with placebo had similar incidences of colorectal cancer (92). Extended follow-up of the patients from the WHI intervention and post-intervention trials over 8 years revealed that the incidence of colon cancer was still decreased among patients receiving CEE plus MPA compared with placebo (87).

Oral Contraceptives

Multiple epidemiologic studies have revealed that OCPs are not a risk factor for colon cancer, but rather protect against this malignancy (See below).

SERMs

In vitro evidence has revealed that both tamoxifen and raloxifene are effective in reducing cell proliferation and viability of colon cancer cell lines, suggesting a possible application in the prevention of colon cancer (124). Unfortunately, the available epidemiologic evidence is limited and controversial regarding the issue of tamoxifen's effects on colorectal cancer risk. A meta-analysis by the Stockholm Breast Cancer Study Group analyzed 4,914 postmenopausal women participating in one of three Scandinavian clinical trials evaluating adjuvant tamoxifen: the Stockholm Trial, the Danish Breast Cancer Group Trial, and the South-Swedish Trial (119). The joint analysis of these three trials revealed that adjuvant tamoxifen therapy in breast cancer patients increased the risk of colorectal cancer (RR, 1.9; 95% CI, 1.1–1.3). In contrast, findings from the NSABP B-14 and the SEER program (125) have failed to confirm an increased risk of colorectal cancer among patients receiving adjuvant tamoxifen therapy. Additional epidemiologic trials are needed to resolve the issue of adjuvant tamoxifen therapy and the risk of secondary sporadic colorectal cancers.

Although some epidemiologic evidence suggests that tamoxifen may be associated with an increased risk of sporadic colorectal cancer, SERMs have been used in the treatment of desmoid tumors associated with hereditary colorectal cancer. Colorectal cancer includes 2 main mechanisms of inheritance: familial adenomatous polyposis (FAP) and hereditary nonpolyposis

colorectal cancer (HNPCC). Desmoid tumors are fibroaponeurotic tumors that occur rarely in the general population but can be found in 12% to 17% of patients with FAP (126). Tamoxifen has been shown to have growth inhibition in desmoid tumor cell lines in an E2-independent mechanism (127). According to the practice guidelines of the Standard Task Force of Colon and Rectal Surgeons, high-dose tamoxifen (120 mg/day) and other SERMs may be used in the treatment of aggressive desmoid tumors. This recommendation is weak (level III) and based on limited descriptive European case series (128,129). The use of tamoxifen in the prevention or treatment of primary colorectal cancer is not advocated.

Phytoestrogens

Increased rates of breast, colon, ovarian, and endometrial cancer are found in Western societies. Phyto-E2s are possible dietary mediators of increased cancer risk that are subdivided into two groups: isoflavonoids and lignans. Isoflavonoids are compounds with inherent estrogenic activity that can lead to low IGF expression and inhibition of aromatase and growth factors, resulting in a possible chemoprotective effect in the breast. Lignans are compounds formed from plant lignan precursors by intestinal microflora. Both isoflavonoids and lignans are found in foods such as whole grain rye bread, soybeans, and red clover. Studies suggest that the development period during which the isoflavonoid is ingested is important in modulation of future cancer risk. Ingestion of soy before or during adolescence may decrease the risk of future breast cancer. However, there is no convincing evidence indicating that soy or other isoflavonoids are protective against breast cancer or colon cancer if ingested during adulthood (118,130). There is a paucity of data regarding the association between isoflavonoids and other cancers affecting women. A case-control study using a Hawaiian group revealed that the high consumption of soy products in adults significantly decreased the risk of endometrial cancer, even after accounting for confounding influences (118,131). Large, population-based studies are needed to determine the effects of isoflavonoids on specific cancer risk, particularly since they are becoming a more common component of the American diet.

Lignans can be indirectly measured via urinary enterolactone. Although women with breast cancer have significantly lower levels of urinary enterolactone, it is unknown whether higher levels of enterolactone are protective against breast cancer or whether they are a marker for an unknown chemoprotective compound associated with a healthier diet. High enterolactone production has been associated with inhibition of colon cancer in animal models, but elevated levels have not been confirmed to be protective against colon cancer in humans (118,130). In contrast, obesity as well as increased dietary fat intake is associated with decreased levels of urinary lignans, suggesting that the increased risk of cancer associated with obesity may be in part related to lignan production.

HORMONES AND THE PREVENTION OF HUMAN CANCERS

Chemoprevention can be defined as the use of specific natural or synthetic chemical agents to reverse, suppress, or prevent the progression toward malignancies. Human carcinogenesis proceeds through multiple discernible stages of molecular and cellular alterations, thus providing the scientific rationale for clinical cancer chemoprevention. The necessary requirements for evaluation of chemoprevention include (a) identification of high-risk individuals based on family history and/or genetic mutations; (b) identification of putative surrogate endpoints or biomarkers for cancer; and (c) the possibility that relatively nontoxic agents

may decrease the risk of a given malignancy. Prospective clinical trials are mandatory for evaluating potential strategies for preventing human malignancies.

Breast Cancer Chemoprevention

SERMs

Reducing the incidence of breast cancer has the potential to provide a major impact on the morbidity of the disease and its treatment, cost to the individual and to society, and overall cancer mortality. Epidemiologic studies indicate that E2-mediated events play a role in the development of breast cancer. Tamoxifen, a SERM, has been utilized as a chemopreventive agent for breast cancer in four randomized, prospective, placebo-controlled clinical trials. Raloxifene, a second-generation SERM, was investigated in the MORE trial, in which the primary endpoint was risk reduction of fracture in postmenopausal women with osteoporosis; the incidence of breast cancer was a secondary endpoint. These 5 studies are reviewed and summarized below.

National surgical adjuvant breast and bowel project breast cancer prevention trial (P-1). In 1992, the National Cancer Institute, in collaboration with the NSABP, initiated the Breast Cancer Prevention Trial (BCPT, P-1) (132). The primary goal was to determine whether tamoxifen administered for 5 years prevented breast cancer in women at high risk, including women 60 years or older, women 35 to 59 with a 5-year predicted risk of breast cancer of at least 1.66%, or women who had a history of lobular carcinoma *in situ* (LCIS). Risk was estimated using the Gail model (133). Each of the 13,388 women enrolled was randomly assigned to receive tamoxifen 20 mg/day or placebo. The median follow-up time was 54.6 months, with 175 cases of invasive breast cancer in the placebo group compared with 89 in the tamoxifen group (RR, 0.51; 95% CI, 0.39–0.66; $p < 0.00001$). Tamoxifen reduced the incidence of ER+ tumors by 69%, but there was no difference in the incidence of ER- tumors. Major toxicities included endometrial cancer (RR = 2.53) and thromboembolic disease (RR = 3.01). The P-1 data has been updated recently, and they have confirmed that the magnitudes of desirable and undesirable effects of tamoxifen are similar to what was observed in the original report (134).

Italian tamoxifen prevention study. Recruitment for this double-blind, placebo-controlled, randomized trial began in October 1992 and ended in July 1997, and included healthy women aged 35 to 70 years (135). The trialist and data-monitoring committee ended recruitment because 26% of women dropped out of this study; 5,408 women were randomized to receive tamoxifen 20 mg/day or placebo for 5 years. Women were allowed to take HRT. The primary endpoints were reduction in the frequency and mortality of breast cancer. At a median follow-up of 46 months, 19 cancers were diagnosed in the tamoxifen arm and 22 among women in the placebo arm ($p = 0.6$). A 2007 update reported (after 11 years of follow-up) that although there was no overall difference in breast cancer between patients receiving placebo versus tamoxifen, high-risk breast cancers were much less often found among women receiving tamoxifen (RR, 0.24; 95% CI, 0.10–0.59) (136).

Royal Marsden Hospital chemoprevention trial. This trial was initiated in 1986 as a preliminary pilot study for the International Breast Cancer Intervention Study (IBIS-I) (137). The aim of this study was to assess whether tamoxifen would prevent breast cancer in healthy women at increased risk for the disease based on family history only. Each participant had at least one first-degree relative under the age of 50 with breast cancer, one first-degree relative with bilateral breast cancer, or one affected first-degree relative of any age and another affected first-degree or second-degree relative. The women were allowed to take HRT during this study. The participants, 2,494 women between the

ages of 30 and 70, were randomized to tamoxifen 20 mg/day or placebo. The median follow-up was 70 months, and 2,471 of the women were analyzed. The frequency of breast cancer was the same for women receiving tamoxifen and placebo (tamoxifen = 34, placebo = 36; RR, 1.06; 95% CI, 0.7–1.7), and there appeared to be no interaction between the use of HRT and the effect of tamoxifen on breast cancer occurrence. An update of this trial reported that contrary to the initial published findings based on 5-year follow-up, there was a clear reduction of invasive estrogen-positive cancers at 10 years (6.2% vs. 5.2%), and the effect was even larger at 15 years (9.6% vs. 7.5%) (138).

International breast cancer intervention study (IBIS). Randomization occurred to tamoxifen 20 mg/day or placebo for 7,152 women, aged 35 to 70 years and at high risk for breast cancer (139). Eligible women had risk factors for breast cancer indicating at least a twofold relative risk among those aged 45 to 70 years, a fourfold relative risk among those aged 40 to 44 years, and a tenfold relative risk among those aged 35 to 39 years. The women enrolled in this study were at moderately increased risk of developing breast cancer, with 60% of the study cohort having a 10-year risk ranging from 5% to 10%. The IBIS-I investigators used a model to predict the absolute 10-year risk of developing breast cancer, but the details of their model have not been published. Use of HRT was permitted, and approximately 40% of women used such therapy at some point during the trial. The primary endpoint was the incidence of breast cancer, including ductal carcinoma *in situ* (DCIS). At a median follow-up of 50 months (7,139 women analyzed), 69 women in the tamoxifen group compared with 101 women in the placebo group developed breast cancer (overall, 32% reduction in breast cancer rate; 95% CI, 8–50; $p = 0.01$). Further long-term follow-up has revealed that for ER-positive invasive tumors, the cumulative incidence in the IBIS-I was reduced after 5 years from 2.0% in the placebo arm to 1.5% in the tamoxifen arm, but after 10 years the values were 4.3% versus 2.9%, respectively (140).

Multiple outcome of raloxifene evaluation. The MORE study was a multicenter, randomized, double-blind trial, raloxifene 60 or 120 mg/day or placebo for 3 years, with the primary endpoint of rate of fracture in postmenopausal women with osteoporosis (141). Breast cancer incidence was a secondary endpoint. A total of 7,705 women were enrolled, all of whom were at least 2 years postmenopausal and no older than 80 years of age. Women who were taking E2 during the previous 6 months were excluded, and 12.3% of women reported a family history of breast cancer. There were 27 cases of invasive breast cancer in the placebo group compared with 13 in the raloxifene group (RR 0.24; 95% CI, 0.13–0.44; $p < 0.001$). There was no difference in breast cancer incidence between the 2 doses of raloxifene. Raloxifene reduced the risk of invasive ER+ breast cancer by 90% (RR 0.10; 95% CI, 0.04–0.24) but did not reduce the risk of ER- breast cancer. The 4-year results from this study, with extension to 4 years after initiation of the trial, were consistent with the results based on the 3-year follow-up (142). The Continuing Outcomes Relevant to Evista (CORE) trial examined the effect of an additional 4 years of raloxifene therapy on the incidence of breast cancer in women in MORE. Over the 8 years of both trials, the incidence of invasive breast cancer and ER-positive breast cancer were significantly reduced, but the incidence of ER-negative tumors was not (143).

The National Surgical Adjuvant Breast and Bowel Project (NSABP) protocol P-2 or the Study of Tamoxifen and Raloxifene (STAR) Trial. This study, opened to accrual on July 1, 1999, was powered to demonstrate superior efficacy or equivalence of either tamoxifen (20 mg/day) or raloxifene (60 mg/day) in reducing the incidence of primary breast cancer. The trial enrolled 19,747 women, and data are available for 19,471 of them—9,726 women in the tamoxifen arm and 9,745 women in the raloxifene arm. All women had a projected 5-year risk of developing breast

cancer of 1.66% or higher as determined by the Gail model. Eligible women included postmenopausal women 35 years or older with no prior history of invasive breast cancer or DCIS. Postmenopausal women aged 35 or older with a history of LCIS were also eligible. Preliminary results of the STAR trial revealed that tamoxifen and raloxifene were as effective as tamoxifen in reducing the risk of invasive breast cancer (RR, 0.70; 95% CI) (122). Recent updates of the STAR trial have shown after 8 years of follow-up that raloxifene is less effective than tamoxifen in reducing invasive cancer, but it is less often associated with endometrial cancer or endometrial hyperplasia (144). In addition, patients treated with raloxifene are diagnosed with endometrial polyps and have fewer hysterectomies while in treatment, compared with women who receive tamoxifen (145).

Aromatase Inhibitors

Aromatase inhibitors (AIs) are being considered for use in breast cancer chemoprevention. In contrast to SERMs, which are competitive inhibitors of E2 at its receptor, AIs suppress plasma E2 levels by inhibiting or inactivating aromatase, the enzyme responsible for the synthesis of E2s from androgenic substrates. This class of compounds has effectively challenged tamoxifen for use as adjuvant therapy in postmenopausal women with ER+ breast cancers, who constitute the majority of patients with breast cancer. Evaluating women with early-stage breast cancer, the ATAC (Arimidex, Tamoxifen, Alone or in Combination) Trialists' Group found that the incidence of contralateral invasive breast cancer was lower in those receiving the third-generation AI (anastrozole [Arimidex]), when compared with tamoxifen, after a median of 100 months of follow-up. For estrogen-positive tumors, disease-free survival and time to survival were both improved significantly among patients receiving anastrozole compared with those given tamoxifen (HR, 0.85, 95% CI, 0.76–0.94; and HR, 0.76, 95% CI, 0.67–0.87). Fracture rates were higher among patients receiving anastrozole than those receiving tamoxifen during active treatment, but there was no difference after the treatment was completed (146).

Prophylactic Oophorectomy

The potential role for oophorectomy as *chemoprevention* (decreased E2 levels) for breast cancer in premenopausal women is an area of active investigation. In genetically uncharacterized premenopausal women, oophorectomy is associated with a 50% reduction in breast cancer incidence, but it also incurs the associated negative effects of a surgically induced early menopause (147,148). In this patient population, where the overall incidence of breast cancer is 1 in 8, it is not standard practice to offer oophorectomy for breast cancer prevention. However, in premenopausal women with germ-line *BRCA1* and *BRCA2* mutations, the cumulative lifetime risk (to 70 years of age) of invasive breast cancer is 60% to 85%, allowing for more serious consideration of prophylactic oophorectomy as a chemoprevention. The prevalence of germ-line *BRCA1* or *BRCA2* in the general population is 0.1% to 0.2%, contributing to a small fraction of all cases of breast cancer, but as many as 10% of cases diagnosed in women younger than 40 years of age and approximately 75% of familial cases. Two publications support the practice of recommending prophylactic oophorectomy after the completion of childbearing in premenopausal women (149,150). Kauff et al. in a prospective study, reported on 170 carriers of *BRCA* mutations with a mean follow-up of 24.2 months, 98 of whom underwent prophylactic salpingo-oophorectomy (149). A 70% risk reduction in breast cancer incidence was identified. Rebbeck et al. in a multicenter retrospective analysis, reported on 551 carriers of *BRCA* mutations with 11 years of follow-up, 259 of whom underwent a prophylactic salpingo-oophorectomy. A 53% risk reduction in breast cancer incidence was identified (150). The reduced risk of a breast cancer diagnosis after salpingo-oophorectomy

in women with *BRCA* mutations confirms an earlier report of a 47% reduction in this patient population (151). The age at risk-reducing depends on the type of mutation and the family history (152). The American College of Obstetricians and Gynecologists has recommended that women who are either at average risk of ovarian cancer or undergoing a hysterectomy for benign conditions, and must make a decision about prophylactic oophorectomy, should be provided an overview of recent studies that suggest a negative health impact (particularly on cardiovascular disease risk) when performed before the age of menopause, particularly in the absence of estrogen replacement (153).

Phytochemicals

Phytochemicals with potential anticancer properties span a wide range of chemical types and activities. Their presence, concentration, and bioavailability in any of thousands of plant species used by humans are variably and incompletely documented. Several studies have specifically examined the effects of vegetable and fruit intake on breast cancer risk. These studies suggest a protective effect of vegetable intake, particularly those rich in carotenoids. Beta-carotene intake has been associated with lower breast cancer risk in several studies (154,155,156). High dietary fiber intake has also been associated with a lower risk of breast cancer (157). The multiplicity of phytochemical actions at different sites in the process of tumorigenesis complicates the investigative effort needed for the development of chemopreventive agents from this class of compounds.

Endometrial Cancer Chemoprevention

Chemoprevention strategies for endometrioid endometrial cancer (EEC) have been based on the observation that exposure to E2 with insufficient progestational stimulation predisposes women to EEC and its precursor lesion, atypical endometrial hyperplasia. While marked obesity, use of exogenous E2, early menarche, and diabetes have been identified as risk factors for the development of EEC, only early menarche has been associated with serous carcinoma, as well as its precursor lesion, endometrial intraepithelial carcinoma (EIC) (158). This observation, as well as other investigational work, supports the existence of a dualistic model for endometrial carcinogenesis, where atypical endometrial hyperplasia and EEC are E2-related, and EIC and serous carcinoma are E2-unrelated. Further delineation of E2-independent pathways of endometrial carcinogenesis will be necessary to develop chemoprevention strategies for serous carcinoma, which accounts for a minority of endometrial carcinomas but a disproportionate number of endometrial cancer deaths. Chemoprevention strategies for EEC, because of its clear association with E2, have been more easily identified, and are described below.

Continuous Combined HRT

Premature termination of one comparison (continuous combined HRT: daily conjugated equine E2 0.625 mg and medroxyprogesterone acetate 2.5 mg) in the WHI primary prevention trial occurred because cardiovascular disease and breast cancer were increased, recognizing that colorectal cancer, endometrial cancer, and osteoporotic fractures were reduced (85). The reduction seen in the incidence of EEC with continuous HRT is in agreement with case-control studies that have documented a reduction in the incidence of this malignancy in women taking continuous combined HRT (108,109,110).

Oral Contraceptives

There is substantial evidence that *ever-use* of OCPs reduces the risk of EEC by approximately 50%. Numerous epidemiologic

studies demonstrate that the reduced risk depends on the duration of OCP use. The risk is reduced by 20% with 1 year of use, 40% with 2 years of use, and 60% with 4 or more years of use (159).

A preliminary analysis of the Centers for Disease Control and Prevention (CDC) Cancer and Steroid Hormone (CASH) study attempted to characterize the protective effect of specific OCP formulations on EEC risk by comparing 187 endometrial cancer cases with 1,320 controls (160). The CASH study determined that continuous OCP formulations provided protective effects (RR, 0.4; 95% CI, 0.2–0.9) while sequential OCPs did not (RR, 2.1; 95% CI, 0.8–5.8). Similarly, in the WHO Collaborative Study of Neoplasia and Steroid Contraceptives, 132 cases of EEC and 835 matched controls were evaluated to determine the protective effects of OCPs on endometrial cancer. Investigators found that the risk of EEC was decreased among women who had a history of combination OCP use (OR, 0.53; 95% CI, 0.29–0.97) (161). In both the CASH and the initial WHO study, combination OCP formulations were not categorized according to the potency of estrogen and progestin, thereby preventing an assessment of the effects on EEC risk according to the potency of the hormonal components.

To better understand the protective effects of combination OCPs, 2 case-control studies have attempted to evaluate progestin and estrogen potency of OCP formulations in relation to EEC risk. Following further enrollment of patients in the WHO Collaborative Study of Neoplasia and Steroid Contraceptives, investigators reported an analysis of 220 cases of EEC and 1,537 controls (162). In this study, a lower risk of EEC was observed with high progestin potency OCP formulations compared with low progestin potency. Although the number of patients using high-potency progestin was very small in this study, the results suggested that high progestin potency OCP formulations could be more protective against EEC. A second case-control study evaluated 316 cases and 501 controls from women in the King or Pierce counties of Washington. The relative risk for women who had used a high progestin potency OCP (RR 0.3; 95% CI, 0.1–0.9) was as low as the relative risk for women using a low-potency progestin (RR, 0.2; 95% CI, 0.1–0.8) (118). These results did not find a potency-dependent protective effect, and suggested that the progestin potency was adequate to achieve a protective effect against endometrial cancer in most combination OCP formulations. The methods of classifying progestin potency were the same in both the WHO study and the Washington State study, thereby eliminating differences in classification as a reason for the different findings from these two studies. Details regarding the specific OCPs taken by case and control subjects were not reported in the Washington State study. The OCP formulations used in the second WHO study contained progestins that are no longer used in OCPs marketed in the United States. A third case-control study using data from the CASH study included 434 endometrial cancer cases and 2,557 control subjects. Overall, high-potency OCPs did not confer more protection than low-potency OCPs. However, among women with a BMI >22.1 kg/m², those who used high progestin potency OCPs had a lower risk of endometrial cancer than those who used low potency OCPs (OR, 0.31; 95% CI, 0.11–0.92); those with a BMI <22.1 kg/m² did not (OR, 1.36; 95% CI, 0.39–4.70) (163). The small number of cases that were overweight (BMI >25 kg/m²) or obese (BMI >30 kg/m²) prevented an analysis with sufficient power to detect a statistically significant modifying effect of overweight status or obesity on the relationship between progestin potency and endometrial cancer risk. However, these findings suggest that high-potency OCPs may be associated with a greater protective effect than low-potency OCPs among women with a higher BMI who are at the greatest risk of endometrial cancer. Obese women often develop Type I endometrioid endometrial cancer. Population-based data have suggested that endometrial cancer-related mortality may be increased among obese women, compared with nonobese women, suggesting

that prevention in this group of high-risk patients may not only affect morbidity but also mortality. Although the biologic mechanism(s) that underlie the protective effect of progestins have not been well characterized, a growing body of evidence has implicated apoptotic and transforming growth factor-beta (TGF- β) signaling events as important mediators of the chemopreventive effect of progestins in the endometrium. Progestins have been shown to induce apoptosis in endometrial glands and stroma, an effect that is modulated by a number of well-known apoptosis-related proteins (164–166).

Intrauterine Devices

Seven studies have reported the relationship between previous copper or nonmedicated intrauterine device (IUD) use and endometrial cancer (167–173). In all but one study, previous IUD use was associated with a decreased risk of EEC. The one study where this relationship was not validated was based on research in China, where the steel ring IUD was utilized, suggesting that this type of IUD is not protective against this malignancy (172). One of the studies to report significant protection against EEC was the landmark CASH study by the Centers for Disease Control (CDC) (167). The majority of the articles reported subgroup analyses regarding factors such as type of IUD and duration/timing of use. In general, no consistent pattern emerged from the articles to suggest that length or timing of use, or type of IUD was associated with an increase or decrease in the risk of EEC (174).

The levonorgestrel-releasing IUD was investigated by Gardner et al. in women taking tamoxifen as adjuvant therapy for breast cancer (175). This preliminary investigation, which included 122 women, randomized 64 patients to the IUD group and 58 patients to the non-IUD group. The authors did an outpatient hysteroscopic assessment with endometrial sampling at entry into the study and after 12 months. A uniform decidual response was seen in all women with the IUD in place. Similar histologic patterns were identified in both groups at baseline and after 12 months. Further follow-up of the patient cohort for an additional year revealed a persistent beneficial effect on prevention of polyps, and no endometrial cancers were diagnosed in the study (175). A second randomized controlled trial of prophylactic IUD in women treated with tamoxifen has been performed by Chan et al. In this study, 113 women who received adjuvant tamoxifen for breast cancer after the completion of postoperative radiation and chemotherapy were randomized to receive an IUD or observational surveillance. Women in the treatment group had a much lower incidence of endometrial polyp at 12 months, compared with the control group (1.8% vs. 15.5%; $p = 0.017$) (176). A statement on the effect of this device on the incidence of EEC in women taking tamoxifen cannot be made, but this warrants further prospective evaluation.

Phytochemicals

The effect of dietary phytochemical consumption on endometrial cancer risk is not clearly delineated. Levi et al. found a strong negative association between beta-carotene and vitamin C intake and endometrial carcinoma among Swiss women, but no clear effect was seen in similar studies in China and the United States (177–179). Barbone et al. demonstrated a protective effect of carotene intake on endometrial cancer (180). Zheng et al. found a weak negative correlation between endometrial cancer and plant food intake in the Iowa Women's Health Study (181). In an analysis of phytoestrogen (i.e., isoflavones, coumestans, and lignans) consumption and endometrial cancer risk, investigators found that a lower risk was associated with increased intake. Obese postmenopausal women consuming relatively low amounts of phytoestrogens had the highest risk of endometrial cancer (OR 6.9; 95% CI, 3.3–14.5), compared with nonobese postmenopausal women consuming high amounts of isoflavones

(182). As is the case with breast cancer, further investigative efforts are necessary to establish the role of phytochemicals in the prevention of endometrial cancer.

Ovarian Cancer Chemoprevention

Although efforts to improve the survival of ovarian cancer patients continue to focus on the development of more effective systemic therapies, the prevention of ovarian cancer is an area of increasing interest. As is the case with breast cancer, assessment of prevention efforts must be analyzed by genetic predisposition. In genetically uncharacterized U.S. women, the lifetime risk of developing ovarian cancer is approximately 1.5%. *BRCA1* mutations increase the risk to 30% to 60%, while women who harbor a mutant *BRCA2* gene have an estimated risk of 10% to 30% (183). Precancerous lesions have not been well-defined for ovarian cancer, although phenotypic changes have recently been described (184). Future chemoprevention trials in ovarian cancer have the potential to utilize biochemical markers of transformation, including cell cycle progression and apoptosis, as surrogate endpoint markers (185,186). Although hysterectomy alone, as well as tubal ligation, has been associated with a decreased risk of developing ovarian cancer, this review will focus on chemoprevention.

Oral Contraceptives

The ability of OCPs to reduce the risk of ovarian cancer has been extensively studied, and it is estimated that there is an overall reduction in risk approximating 40% (187). The adjusted odds ratio for ever-use of OCPs has consistently been shown to be between 0.6 and 0.7 (188–190). The degree of protection and the length of protection appear to be associated with the duration of OCP usage. Prolonged risk reduction has been reported when OCPs are used longer than 4 to 6 years, and minimal benefit has been observed if utilization is restricted to a period of 6 months to 2 years (191–194). One of the largest case-control studies to date is the CDC CASH study. In this study, 546 women with ovarian cancer and 4,228 control subjects from eight population-based cancer registries were compared. Women with a history of OCP use had a 40% reduced risk of epithelial ovarian cancer (RR, 0.6; 95% CI, 0.5–0.7) when compared with women with no history of OCP use. This protective effect was evident with as little as 3 months of OCP use and continued for up to 15 years following discontinuation of OCP use. OCP-mediated risk reduction was independent of the histologic type of ovarian cancer (195).

It has been estimated that more than half of all ovarian cancers in the United States could be prevented by OCP usage for at least 4 to 5 years (189,190,196). The protective effect of OCPs appears to be consistent across races, as John. et al. demonstrated a reduction in risk of 0.6 in African-American women with OCP use of 6 years or more (197). The estrogen/progestin content of any particular OCP and how it relates to protection against ovarian carcinoma needs further investigation. Ness et al. demonstrated identical risk reduction for OCPs with high-estrogen/high-progesterone content, when compared with low-estrogen/low-progesterone content pills (198). Schildkraut et al., in an observational study, recently reported that low-progesterone OCP formulations were associated with a significantly higher risk of ovarian cancer when compared with high-progesterone potency OCP formulations (199).

The lifetime risk of ovarian cancer is approximately 45% in *BRCA1* carriers and 25% among *BRCA2* carriers (200). In women carrying *BRCA1*- or -2 mutations, Modan et al. concluded that OCPs did not protect against ovarian cancer in Israeli Jewish women. However, Narod et al. showed that the use of OCPs in Jewish and non-Jewish women with *BRCA* mutations was strongly protective against this malignancy, with

an odds ratio of 0.44 (95% CI, 0.28–0.68) (201,202). Important differences exist between the two studies, most notably that the controls in the Narod et al. study were all mutation carriers, while in the Modan et al. study only 1.7% of the controls carried the mutation. The use of OCP as a chemopreventive agent against ovarian cancer should be considered in *BRCA* carriers.

Little is known about the mechanism of the protective effect of OCPs against ovarian cancer, although it has been postulated that a major mechanism of OCP protection relates to a decrease in ovulatory cycles. There are data to suggest that an increased rate of apoptosis in aberrant epithelial cells, secondary to the progestational component, may also play an important role. Rodriguez et al. examined the effect on ovarian epithelium of levonorgestrel in 130 ovulatory macaque monkeys (203). These authors demonstrated significantly increased apoptotic cell counts in the ovarian epithelium of animals exposed to progesterone, leading to the hypothesis that progestin-induced apoptosis of the ovarian epithelium is responsible for the chemopreventive effect of OCPs.

Colon Cancer Chemoprevention

Colorectal cancer is the second most common cause of cancer death in the U.S. (behind only lung cancer, as breast and prostate cancer are sex-linked), and the third most common cause of cancer death for U.S. women. In 2012, there were an estimated 70,040 new cases of colorectal cancer diagnosed in U.S. women, and an estimated 25,220 deaths (204).

Hormone Replacement Therapy

Two recent meta-analyses have calculated an approximate one-third reduction in risk of colon cancer among current or recent users of HRT, compared with about a 10% to 20% reduction among ever-users versus never-users of HRT (204,205). Although Nanda et al. determined that *rectal* cancer was not related to HRT usage, Grodstein et al. determined a reduction in risk for ever-users versus never-users (RR, 0.81; 95% CI, 0.72–0.92). Both meta-analyses are limited by lack of consistent and accurate reporting on type of HRT, as well as lack of control for potential confounders, such as diet, site of cancer, family history, or screening. Adenomatous polyps precede colorectal cancers by a decade or more, thus any association between their presence and HRT is of obvious interest. Two case-control studies have found a protective effect of HRT on the development of adenomatous polyps (206,207). The prospective Nurses' Health Study reported a decreased risk of large adenomatous polyps for current users (RR, 0.74; 95% CI, 0.55–0.99), whereas there was no association between small adenomatous polyps and HRT (208).

The Women's Health Initiative confirmed what other observational studies have suggested. This randomized, controlled primary prevention trial, in which 16,608 postmenopausal women aged 50 to 79 years with an intact uterus at baseline were recruited by 40 U.S. clinical centers in 1993 to 1998, showed a reduction in the incidence of colorectal cancer in those women taking combined estrogen and progesterone therapy. In 8,506 women prescribed estrogen and progesterone and in a placebo control group of 8,102 women, a hazard ratio of 0.63 with a nominal 95% CI of 0.43 to 0.92 was observed. Colorectal cancer rates were reduced by 37% (10 vs. 16 per 10,000 person-years) (85,208).

There are several hypotheses regarding a protective effect of HRT on the risk of colorectal cancer, including alteration of the predominant ER isoform, as well as E2's ability to decrease production of secondary bile acids.

Oral Contraceptives

The relationship between OCPs and colorectal cancer has not been clearly delineated. Recently, a large case-control study

was conducted in northern Italy between the years 1985 and 1992, with 709 cases of colorectal cancer and 992 control subjects (209). Ever-use of OCPs versus never-use through use of a multiple logistic regression was associated with a reduced risk of colorectal cancer (RR, 0.58; 95% CI, 0.36–0.92). Further, there was a suggestion that duration of use (i.e., more than 2 years) was associated with increased protection. More recently, the Nurses' Health Study cohort identified 502 cases of colorectal cancer among participants between 1980 and 1992 (210). Among women using OCPs, use for 6 or more years was associated with a 40% reduction in risk of colorectal cancer (RR, 0.60; 95% CI, 0.40–0.89). The trend for the duration effect was statistically significant ($p = 0.02$). Several smaller studies, all with serious limitations in study design and/or execution, have reported varying results regarding the relationship between OCPs and colorectal cancer.

HORMONES AND THE TREATMENT OF HUMAN CANCERS

The role of hormones in the treatment of human malignancies has been most extensively examined in the management of breast carcinoma. Now, the potential to exploit hormone-signaling pathways in the management of other malignancies, affecting both men and women, is rapidly becoming a reality. As our understanding of both the molecular biology of cancer and the human genome expands, targeted therapeutics, including hormonal manipulation, will undoubtedly assume a more critical role in the management of human malignancies.

Breast

Overview

When considering hormonal treatment (HT) of breast cancer, it is important to distinguish between premenopausal women, in whom the primary source of estrogen is the ovaries, and postmenopausal women, in whom aromatization of androgens in the peripheral tissue is the major source of estrogen production. In premenopausal women, removal of the ovaries via surgical or radiologic ablation, or inhibition of ovarian estrogen production with a gonadotropin-releasing hormone (GnRH) analog, results in marked decrease in estrogen levels. SERMs, most notably tamoxifen, are a treatment option for both premenopausal and postmenopausal women with ER-positive disease; they reduce tumor cell proliferation by binding to and blocking the activation of ERs. In premenopausal women, treatment with tamoxifen plus ovarian ablation may provide added benefit by decreasing estrogen effect by two complementary mechanisms.

AIs interfere with estrogen production by targeting the peripheral aromatization of androgens. In postmenopausal women, in whom peripheral tissue production of estrogen is responsible for the majority of circulating estrogen, AIs are a logical choice in the selection of HT. The role of AIs in premenopausal women is less clear, owing to the high level of ovarian estrogen in this patient population.

Adjuvant Hormonal Therapy for Early-Stage Breast Cancer

Postmenopausal Women

Tamoxifen prescribed for approximately 5 years after surgery to patients with early ER-positive breast cancer remains the current standard of adjuvant therapy worldwide. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) conducted

Table 16.2 Hormone Receptor Status: Effect on Response Rate in Early-Stage Disease

Receptor Status	N	Reduction in Recurrence % (95% CI)	Reduction in Mortality % (95% CI)
ER ⁺ , PgR ⁺	7,000	37 (±6)	16 (±8)
ER ⁺ , PgR ⁻	2,000	32 (±12)	18 (±14)
ER ⁻ , PgR ⁺	602	23 (±24)	9 (±28)
ER ⁻ , PgR ⁻	2,000	1 (±14)	1 (±14)

Note: All patients were treated with tamoxifen.

Source: Tamoxifen for early breast cancer: an overview of the randomised trials. Early Breast Cancer Trialists' Collaborative Group. *Lancet*. 1998;351:1451-1467.

a meta-analysis to assess recurrence and mortality rates among randomized trials of women with primary breast cancer who received adjuvant tamoxifen therapy or placebo. Table 16.2 details the reduction in recurrence and mortality, stratified by ER and PR status, revealing that women with hormone receptor-positive tumors experience a more significant improvement in both endpoints. Conversely, women with hormone receptor-negative tumors received little, if any, benefit from HT. Furthermore, the EBCTCG established that hormone receptor-positive women receiving tamoxifen demonstrated a 21%, 28%, and 50% reduction in recurrence. Additionally, this group of women experienced a 14%, 18%, and 28% reduction in mortality in the treatment groups of 1 year, 2 years, and approximately 5 years, respectively, with consistent benefits across various tamoxifen dosing regimens (20 to 40 mg/day) (211). Although the efficacy of tamoxifen in the adjuvant setting has been established, the toxicity profile of this agent, including an increased risk of EEC and thromboembolic events, has prompted investigative efforts into alternative, adjuvant anti-estrogenic therapies, specifically AIs.

In 2002, anastrozole alone was approved as adjuvant treatment for early breast cancer. The ATAC trial included 9,366 postmenopausal women with operable, early, invasive breast cancer who had completed primary treatment and were candidates for adjuvant HT. The data demonstrated superior efficacy of anastrozole, when compared with tamoxifen, in improving disease-free survival in postmenopausal women with hormone receptor-positive or unknown early-stage breast cancer. Disease-free survival was significantly longer for patients on anastrozole alone than for those who received tamoxifen alone (HR, 0.83; 95% CI, 0.71–0.96; $p = 0.013$) or the combination of both (HR 0.81; 95% CI, 0.70–0.94; $p = 0.006$). The combination was not significantly different from tamoxifen alone (HR, 1.02; 95% CI, 0.89–1.18; $p = 0.8$). The disease-free survival estimates at 3 years were 89.4%, 87.4%, and 87.2% on anastrozole, tamoxifen, and the combination, respectively. Incidence of contralateral breast cancer was significantly lower with anastrozole than with tamoxifen (OR, 0.42 [0.22 – 0.79]; $p = 0.007$) (212). The ATAC data were recently updated with 68 months of follow-up, and the benefit of the anastrozole over tamoxifen was maintained (213). After publication of the ATAC data, the American Society of Clinical Oncology (ASCO) Health Services Research Committee suggested that a 5-year course of tamoxifen remain the standard adjuvant HT, pending updated data from the ATAC trial and other trials of third-generation AIs in the adjuvant setting (214). Goss et al. conducted a double-blind, placebo-controlled trial evaluating the effectiveness of 5 years of letrozole in 5,187 postmenopausal women with early-stage breast cancer who had completed 5 years of tamoxifen therapy (215). The estimated 4-year disease-free survival rates were 93% for the letrozole group and 87% for the control group ($p < 0.001$), suggesting

that in this subset of breast cancer patients, AI therapy after tamoxifen provides a survival advantage. An analysis of the post-unblinding data revealed that among the 2,594 women initially randomized to placebo, 1,655 women chose to receive open-label letrozole. At 54 months, a statistically significant benefit in disease-free survival favored the crossover patients (HR, 0.31; $p < 0.0001$) (216).

The Breast International Group (BIG) 1-98 study, a randomized, phase 3, double-blind trial, compared 5 years of treatment with various adjuvant endocrine therapy regimens in postmenopausal women with hormone receptor-positive breast cancer: letrozole, letrozole followed by tamoxifen, tamoxifen, and tamoxifen followed by letrozole. A total of 8,010 women with data that could be assessed were enrolled: 4,003 in the letrozole group and 4,007 in the tamoxifen group. After a median follow-up of 25.8 months, 351 events had occurred in the letrozole group and 428 events in the tamoxifen group, with 5-year disease-free survival estimates of 84.0% and 81.4%, respectively. As compared with tamoxifen, letrozole significantly reduced the risk of an event ending a period of disease-free survival (HR, 0.81; 95% CI, 0.70–0.93; $p = 0.003$), especially the risk of distant recurrence (HR, 0.73; 95% CI, 0.60–0.88; $p = 0.001$). In postmenopausal women with endocrine-responsive breast cancer, adjuvant treatment with letrozole, as compared with tamoxifen, reduced the risk of recurrent disease, especially at distant sites (217). These large randomized trials, as well as others, have assessed the benefit of third-generation aromatase inhibitors anastrozole, letrozole, and exemestane, compared with 5 years of tamoxifen (13,146,218–220). These trials have established that AIs are associated with reduced recurrence rates and improved disease-free survival, but the trials have *not* demonstrated a statistically significant improvement in overall survival. A recent meta-analysis with greater statistical power that reviewed the randomized trials confirmed that the use of aromatase inhibitors was associated with improved disease-free survival. This meta-analysis also showed a statistically significant—albeit modest—improvement in overall survival for patients who took aromatase inhibitors for 2 to 3 years after treatment with tamoxifen for 2 to 3 years (13). However, no overall survival benefit was seen in those who received AIs as initial therapy. In another meta-analysis, Amir et al. found that the cumulative toxicity of AIs when used as up-front treatment may explain the lack of overall survival benefit, despite improvements in disease-free survival (221). In this study, up-front treatment with AIs was associated with nonstatistically significant higher odds of death without recurrence, compared with the use of tamoxifen alone or switching from tamoxifen to aromatase inhibitors (OR, 1.11; 95% CI, 0.98–1.26; $p = 0.09$). Conversely, switching from tamoxifen to AIs was associated with decreased odds of death without recurrence, compared with up-front tamoxifen for 5 years (OR, 0.75; 95% CI, 0.58–0.98; $p = 0.04$) (309). In summary, beginning with tamoxifen and switching to aromatase inhibitors is likely the best balance between efficacy and toxicity.

Many issues regarding the adjuvant use of AIs remain unsettled, including the optimal duration of treatment, the optimal sequencing with tamoxifen, and the optimal AI. ASCO guidelines published in 2010 recommend that postmenopausal women with hormone receptor-positive breast cancer consider incorporating an AI therapy at some point during adjuvant treatment, either as up-front therapy or as sequential treatment after tamoxifen. The optimal timing and duration of endocrine treatment remain unresolved. The ASCO Update Committee supports careful consideration of adverse effect profiles and patient preferences in deciding whether and when to incorporate AI therapy (222).

Premenopausal Women

The optimal adjuvant therapy for premenopausal women with hormone-responsive breast cancer remains uncertain,

despite numerous clinical trials over the past 60 years that have attempted to address this issue. Various strategies of ovarian suppression/ablation, tamoxifen, and/or chemotherapy alone or in combination have been evaluated. The EBCTCG overview analysis has confirmed that adjuvant tamoxifen confers a survival benefit for ER-positive patients, regardless of menopausal status. Accumulated clinical trial data as well as the EBCTCG overview analysis have confirmed that ablation of functioning ovaries significantly improves survival in breast cancer patients younger than 50 years of age, at least in the absence of chemotherapy (223). In the last several years, several investigations have supported the utilization of tamoxifen and ovarian suppression/ablation as adjuvant therapy in premenopausal women with early-stage, receptor-positive breast cancer (224–228).

Two basic strategies exist to abrogate ovarian function. Ovarian suppression (OS) refers to the use of temporary means to suppress ovarian function, generally with luteinizing hormone releasing hormone (LHRH) analogs. Ovarian ablation (OA) refers to permanent strategies using either oophorectomy or ovarian radiation. Despite the clear benefits seen with OA/OS as compared with no adjuvant therapy, the additional benefits of OA/OS in women who have also received chemotherapy is less clear. With the known advantages of both chemotherapy and OA/OS alone as monotherapies, additional studies were designed to evaluate the benefit of adding OA/OS to standard chemotherapeutic regimens, as well as the reverse scenario of assessing the benefit of chemotherapy when added to OS/OA. In aggregate, these studies do not show a clear overall survival benefit with the addition of OS/OA to chemotherapy, although a small benefit appears to emerge, particularly in younger women with hormone-responsive disease.

There is a persistent need to define optimal endocrine therapy in premenopausal women with hormone receptor-positive breast cancer. Several ongoing trials are expected to definitively address the various roles of combining chemotherapy, OS/OA, tamoxifen, and AIs in premenopausal patients with early-stage hormone receptor-positive breast cancer. Contemporaneous trials, such as the Suppression of Ovarian Function Trial (SOFT), Tamoxifen and Exemestane Trial (TEXT), Premenopausal Endocrine Responsive Chemotherapy (PERCHE), and Austrian Breast and Colorectal Cancer Study Group (ABCSG), hopefully will provide direction. Additionally, biomarker and pharmacogenomic data will help further supplement individualized patient decision-making.

Consideration of maintaining fertility is an issue for a subset of premenopausal women with early-stage breast cancer. The prevention of premature ovarian failure after cytotoxic chemotherapy utilizing GnRH analogs for temporary ovarian suppression has been investigated by several studies. Several Phase II studies have reported a high rate of preserved menstruation in treated patients. Other studies have suggested no benefit, with tamoxifen use in either case not being routinely considered. Recently, in a prospective study, Munster et al. randomized premenopausal women to receive either triptorelin or no triptorelin during adjuvant chemotherapy. The women were further stratified by age (<35, 35 to 39, and >39 years); estrogen receptor status; and chemotherapy regimen. Objectives included the resumption of menses and serial monitoring of FSH and inhibin A and B levels. The authors concluded that when women were stratified for age, estrogen receptor status, and treatment regimen, amenorrhea rates on triptorelin were comparable with those seen in the control group (229).

Hormonal Therapy for Metastatic Breast Cancer

Metastatic breast cancer (MBC) remains a major therapeutic challenge, whether it is the first presentation of breast cancer or a recurrence after prior treatment of early-stage disease.

Median survival of patients with metastatic breast cancer is between 2 and 3 years. In premenopausal women, regression of advanced breast cancer as a result of prophylactic oophorectomy was first described in 1896 (230). In multiple series of premenopausal women with metastatic breast cancer, where hormone receptor status was unknown, oophorectomy resulted in cancer regression in 30% to 40% of cases. In premenopausal women with known ER-positive tumors, a 50% to 60% regression after oophorectomy has been noted.

Endocrine therapy for postmenopausal women with advanced, hormonally responsive ER+ breast cancer is based on the observation that greater than three-fourths of these patients respond to HT. In contrast, only 11% of patients with hormone receptor-negative tumors show a response. Tamoxifen was the gold standard of first-line HT for metastatic breast cancer for more than 40 years. However, third-generation AIs have eclipsed tamoxifen in the treatment of postmenopausal women with metastatic estrogen-dependent breast cancer (231). Several large, multinational randomized trials have been undertaken to assess the efficacy and toxicity of AIs in breast cancer in the advanced setting. Results from these trials have demonstrated the superiority of third-generation AIs over tamoxifen in advanced disease (232–235).

Importantly, AIs were demonstrated to exhibit a much less adverse toxicity profile compared with tamoxifen, particularly concerning development of deep vein thrombosis and pulmonary emboli (236). Such evidence has led to the approval of third-generation AIs as first-line therapeutics for advanced breast cancer.

Fulvestrant, an anti-estrogen receptor (anti-ER) drug, is a Selective ER Down Regulator (SERD) that destroys ERs and decreases the number of PRs in breast cancer cells. Fulvestrant is now approved for tamoxifen-resistant tumors. Furthermore, it has been established that fulvestrant and exemestane are equally active and well-tolerated in a meaningful proportion of postmenopausal women with advanced breast cancer who have experienced progression or recurrence during treatment with a nonsteroidal AI (237).

Endometrium

Hormonal Treatment of Endometrioid Endometrial Cancer

The median survival of women with advanced or recurrent EEC is less than 1 year. When the best chemotherapeutic regimen available is used, the complete response rate in those patients with advanced-stage EEC is only 22%. Histologic grade is known to be a predictor of stage and survival, with grade 3, poorly differentiated cancers portending a higher risk of extrauterine disease and thus poorer survival. Furthermore, Carcangiu et al. evaluated 183 patients with EEC, establishing a correlation between the International Federation of Gynecology and Obstetrics (FIGO) grade and hormone receptor expression (238). The recognized association of higher grade with lower ER/PR expression carries implications for the use of HT in advanced EEC. A majority of advanced cases of EEC are grade 3 lesions, limiting the use of HT in this patient population.

Advanced or Recurrent Endometrioid Endometrial Cancer

Progestational agents. The use of progestational agents in women with advanced or recurrent EEC has been under investigation for several decades. Several different types of progestational agents have been investigated, including hydroxyprogesterone caproate (Delalutin), medroxyprogesterone acetate (MPA, Provera), and megestrol acetate (Megace). A majority of

studies evaluating this treatment modality have included small numbers of patients with no stratification for well-recognized predictors of response. In the last decade, several studies with larger patient sample size, clearer eligibility criteria, and clearer definition of response and toxicity have evaluated the effectiveness of progestational agents in the treatment of advanced or recurrent EEC. Thigpen et al. evaluated women with advanced or recurrent EEC who were randomized to receive either oral MPA 200 mg/day or oral MPA 1,000 mg/day until unacceptable toxicity or disease progression (239).

The overall response rates (complete plus partial) favored the low-dose regimen (25% and 16% for low- and high-dose regimens, respectively). The median progression-free survival (PFS) time was 3.2 months for the low-dose regimen and 2.5 months for the high-dose regimen. There was an association, including patients receiving both dosing regimens of MPA, between response and histologic grade, with well-differentiated tumors responding more frequently than poorly differentiated lesions. The response rates were 37% (22 of 59 patients), 23% (26 of 113 patients), and 9% (12 of 127 patients) for those with grade 1, 2, or 3, respectively. There also was a noteworthy correlation between response and receptor content. The response rate was 8% (7 of 86 patients) for patients who were PR negative and 37% (17 of 46) for patients who were PR positive ($p < 0.001$). The response rate was 7% (4 of 55) for patients who were ER negative and 26% (20 of 77) for patients who were ER positive ($p = 0.005$). An association between receptor status and tumor grade was established as well. After adjusting for tumor grade, PR concentration remained an important predictor of survival. In summary, the overall response rate for the progestational agents in women with advanced or recurrent EEC is relatively low. However, progestational agents remain a therapeutic alternative for this patient population, where significant comorbid conditions frequently exist, particularly in those women who can predictably expect a higher response based on grade and receptor content.

Combination chemotherapy and progestational agents. Combining chemotherapy with hormonal therapy is an area of active research. Pinelli et al. prospectively treated 13 advanced EEC patients with carboplatinum 300 mg/mm² every 4 weeks for 6 cycles. Subsequent to the chemotherapy, Megace 80 mg/day for 3 weeks alternating with tamoxifen 40 mg/day for 3 weeks was prescribed. A complete response was obtained in 30% of patients, a partial response in 46%, stable disease in one patient, and disease progression in 2 patients (240). There are ongoing investigations to study the role of combination cytotoxic chemotherapy and HT in the treatment of advanced or recurrent EEC.

Selective estrogen receptor modulators. SERMs have been and continue to be investigated for HT of EEC. Tamoxifen was studied by the GOG in a phase 2 study of patients with advanced or recurrent EEC. At a dose of 20 mg twice daily, only 10% of 68 patients demonstrated objective response, but response occurred more commonly in grades 1 and 2 tumors (23% and 14%, respectively) compared with grade 3 tumors (3%) (241). From pooled reports of eight other studies including 257 patients, 22% of patients with advanced EEC responded to tamoxifen, but with a wide range of responses (0 to 53%) (242).

Tamoxifen can increase PgR content in endometrial cancer tissues. Theoretically, this increase would enhance the activity of progestins, which frequently downregulate PgR within the target tissue, shortening the duration of response. Clinical studies on alternating treatment with tamoxifen and progestin have provided conflicting results (239,241,243–246). Other SERMs are also under investigation, including raloxifene and its metabolite, LY353381.HCl (arzoxifene). First-generation SERMs, such as tamoxifen, have mixed estrogenic agonist and antagonist activity, whereas second-generation SERMs, such as raloxifene, have more selective E2 antagonism. Arzoxifene (LY353381),

a third-generation SERM, is a potent E2 antagonist in mammary and uterine tissues, with enhanced bioavailability and antiestrogenic activity compared with raloxifene. This SERM elicited a complete response in 1 and a partial response in 8 of 29 patients with advanced EEC, with an overall response rate of 31%. The median duration of response was 13.9 months, with minimal toxicity. All responses occurred in progestin-sensitive patients. The relatively high response rate and the favorable toxicity profile make this agent worthy of further investigation (247,248).

Aromatase inhibitors. Anastrozole and letrozole are active, highly selective, nonsteroidal, competitive inhibitors of the enzyme aromatase. It has been shown that significant amounts of aromatase are found in endometrial cancer, with low amounts being present in the surrounding normal endometrial tissue. Rose et al. recently found that in 23 patients anastrozole at 1 mg a day for 28 days has minimal activity, with only a 9% partial response rate and a progression-free interval of 1 to 6 months in women with advanced EEC (249).

The National Cancer Institute of Canada completed a multicenter phase 2 trial evaluating letrozole in postmenopausal women with recurrent or advanced endometrial carcinoma. Thirty-two eligible patients were treated with letrozole at 2.5 mg daily continuously. Of the 28 patients evaluated for response, one complete and two partial responses were noted; overall response was 9.4% (95% CI, 2–25). Eleven patients had stable disease for a median duration of 6.7 months (range, 3.7–19.3 months). In conclusion, letrozole is well-tolerated, but it has little overall activity in this cohort of women with endometrial cancer (250).

Antigonadotropins. Antigonadotropins, such as danazol, antagonize pituitary gonadotropin release and limit adrenal and estrogen production. Danazol has yet to be clinically tested in patients with endometrial cancer. However, *in vitro* studies have shown it to inhibit endometrial tumor cell migration (similar to MPA) and inhibit invasive activity (not demonstrated by MPA) (251,252). The clinical effects of danazol on endometrial hyperplasia have been evaluated (253). Of 15 patients with pathologically proven hyperplasia, all were successfully converted to atrophic endometrium by day 90 of danazol 400 mg/day. Given the perceived low toxicity of danazol compared with conventional chemotherapy, the lack of effective agents in this disease, and a theoretical rationale for its activity in endometrial cancer, a phase 2 trial was undertaken by the GOG (GOG-0180). The results of this trial showed that danazol has minimal activity in advanced, recurrent, or persistent endometrial carcinoma (254). Fulvestrant, a pure antiestrogen hormonal agent without any estrogen agonist activity, has also been tested in a phase II GOG trial (protocol 188), but showed limited activity in ER positive or ER negative tumors (255).

In a recent Cochrane Analysis, the authors found insufficient evidence that hormonal treatment in any form or dose, or as part of combination therapy improves the survival of patients with advanced or recurrent endometrial cancer (Table 16.3). In the absence of a proven survival advantage, the decision to use any type of hormonal therapy should be individualized with the intent to palliate the disease. It is debatable whether outcomes such as quality of life, treatment response, or palliative measures such as relieving symptoms should take preference over overall and PFS as the major objectives of future trials (256).

Adjuvant Therapy for Endometrioid Endometrial Cancer

The use of progestational agents as adjuvant therapy for stages I and II EEC has been investigated by von Minckwitz et al. (257). They conducted a randomized trial of 388 patients with early-stage EEC who received either MPA ($n = 133$), or tamoxifen ($n = 121$)

Table 16.3 Selected Trials of Hormonal Therapy in Metastatic Endometrial Cancer

Treatment	No. of Patients	RR (%)	PFS (mo)	OS (mo)	Reference
MPA 200 mg/d	331	17	4	10.4	(289)
MPA 200 mg/d	145	25	3.2	11.1	(239)
MPA 1000 mg/d	154	15	25	7.0	(239)
Tamoxifen 20 mg b.i.d	68	10	1.9	8.8	(241)
Tamoxifen 20 mg b.i.d	45	53.4	NR	NR	(290)
MA + tamoxifen	42	18	NR	12.0	(244)
MA 160 mg for 3 wk, then tamoxifen 40 mg for 3 wk, alternating	61	26.8	2.7	14.0	(245)
Arzoxifene	34	31	13.9	NR	(248)
Goserelin acetate 3.6 mg monthly, subcutaneously	17	35	20	NR	(291)
Goserelin acetate 3.6 mg monthly, subcutaneously [41]	40	12	1.9	7.3	(292)
Anastrozole 1 mg/day [42]	23	9	1.0	6.0	(249)
Letrozole 2.5 mg/day [43]	28	9.4	NR	NR	(250)

Abbreviations: RR, response rate; PFS, progression-free survival; OS, overall survival; MPA, medroxyprogesterone acetate; NR, not reported; MA, megestrol acetate.

orally for 2 years, or were observed only ($n = 134$) after surgical therapy. After 56 months of follow-up, no benefit was observed from adjuvant progestin or tamoxifen therapy after surgical treatment in early-stage EEC. However, given the low frequency of recurrence in this patient population, larger randomized studies are needed to fully evaluate the role of progestational agents as adjuvant therapy in early EEC.

Progestational Agents as Primary Therapy for Endometrioid Endometrial Cancer

Several small series have retrospectively reported on the use of progestational agents alone, not preceded by hysterectomy, in the treatment of patients with EEC, either because of the desire to maintain fertility or because of comorbid conditions. No randomized, controlled studies evaluating progestational agents in either clinical scenario are available. Montz et al., in a prospective pilot study, reported on the use of the progesterone IUD in women with presumed stage IA, grade 1 EEC, who were at significant risk for perioperative morbidity (258). Follow-up endometrial biopsies were negative in 7 of 11 patients at 6 months, and in 6 of 8 patients at 12 months. Recently, Ramirez et al. searched MEDLINE and other databases for English language articles describing patients with grade 1 EEC treated with hormonal therapy. Ultimately, 81 patients in 27 articles were included in the study. Sixty-two patients (76%) responded to treatment. The median time to response was 12 weeks (range, 4–60 weeks). Fifteen patients (24%) who initially responded to treatment recurred. The median time to recurrence was 19 months (range, 6–44 months). Ten (67%) of the patients with recurrence ultimately underwent total abdominal hysterectomy. Residual endometrial carcinoma was found in 6 of the 10 patients (60%). Twenty patients were able to become pregnant at least once after completing treatment. No patients died of their disease. Further investigation is needed into this approach to the primary management of EEC (259). More recently, Westin et al. from M. D. Anderson Cancer Center prospectively evaluated, in a single-arm phase 2 study, the levonorgestrel intrauterine system (LIUS) in the treatment of complex adenomatous hyperplasia (CAH) and EEC grade 1. After confirmation of no extrauterine disease, dilation and curettage was performed and the LIUS was placed. Endometrial biopsies were performed every 3 months. The primary efficacy end-point was pathological response rate (RR) at 12 months, defined as

complete response (CR) and partial response (PR). CR is defined as no abnormality or as hyperplasia without atypia in CAH or EEC patients. PR is defined as CAH in EEC patients. Twenty-six evaluable patients have been enrolled thus far: 18 had CAH, and 8 had EEC. The overall 12-month response rate was 58%. At 12 months, 11 patients had CR (1 with EEC, 10 with CAH); 1 patient had PR (EEC); 2 patients had stable disease (CAH); and 5 patients had progressive disease (4 with EEC, 1 with CAH). Seven of the 26 patients did not reach the 12-month mark in the study. After stratification for histology, response rate was 85% for CAH (13 evaluable) and 33% for EEC (6 evaluable). The LIUS has encouraging activity in CAH and EEC. Response may be predicted by presence of exogenous progesterone effect (260).

Ovary

Hormones and their receptors have been associated with ovarian cancer and may be related to its causation. Some data suggest that hormonal therapies may have an effect on ovarian cancer in palliative settings (261). Several investigators have established that hormone receptors are expressed in epithelial ovarian cancer, and that significant alterations occur with malignant transformation. Rao and Slotman reviewed 45 series, including 2,508 ovarian cancer patients, and reported that 67% of tumors expressed ER and 47% expressed PR (262). The expression of the ERs and PRs has been found to correlate with long-term survival in invasive ovarian cancer. The ER-PR⁺ phenotype predicted a more favorable tumor biology and long-term survival (263). A large number of hormonal agents have been evaluated in the treatment of ovarian cancer, including SERMs, E2, progestins, androgens, AIs, and GnRH agonists. Progestin therapy in patients with advanced ovarian cancer has a global response rate of 8% to 15% (264). Tamoxifen, in preclinical studies, inhibits ovarian cell growth *in vitro*, providing rationale for the use of this agent in the treatment of ovarian cancer. Several studies have evaluated the activity of single-agent tamoxifen in the treatment of advanced ovarian cancer (Table 16.4) (265–282).

Perez-Garcia and Carrasco reviewed the literature evaluating single-agent tamoxifen in the treatment of patients with advanced ovarian cancer, most of whom were heavily pretreated and refractory to chemotherapy (283). A total of 648 patients were included with an overall response rate (ORR) of 13% (95% CI, 10.4–15.6; range, 56), including a 4% complete response

Note: CR, complete response; CT, chemotherapy; NS, not stated; OR, overall response; PR, partial response; SD, stable disease.

^aOnly evaluable patients are included (but prior CT lines refer to the whole population).

^bWith a loading dose of 100 mg/24 h during 1 d (Osborne et al. [272]), 40 mg/24 h during 7 d (Weiner et al. [282]), and 40 mg/24 h during 30 d (Ahlgren et al. [265]).

^cCalculated over the number of patients included in trials that report these data.

rate and a 9% partial response rate. In 38% of patients, stable disease was noted. These results are not entirely dissimilar from those seen with progestins.

Gershenson et al. recently studied the role of tamoxifen in women with low-grade serous ovarian tumors. They identified 64 patients with recurrent low-grade serous carcinoma of the ovary or peritoneum. Patients' median time to progression (TTP) and median overall survival (OS) were 7.4 and 78.2 months, respectively. Patients received 89 separate hormonal patient regimens, which produced an overall response rate of 9% (6 complete responses and 2 partial responses). Sixty-one percent of the patient-regimens resulted in a PFS of at least 6 months. Patient regimens involving ER+/PR+ disease produced a longer median TTP (8.9 months) than patient regimens involving ER+/PR– disease (6.2 months; $p < 0.053$). This difference approached, but did not reach statistical significance. The authors concluded that hormonal therapies have moderate antitumor activity in patients with recurrent low-grade serous carcinoma of the ovary

or peritoneum. Further study is warranted to determine whether ER/PR expression status is a predictive biomarker for this rare cancer subtype (284).

The role of GnRH agonists in the management of refractory ovarian cancer has been evaluated in multiple studies and has been summarized by Paskeviciute et al. (285). GnRH agonists induced an overall objective response in 8.5% of refractory ovarian cancer patients, with disease stabilization in 23% of these women.

Several investigators have compared chemotherapy and hormonal therapy with chemotherapy alone, primarily in patients with advanced ovarian cancer. However, these studies had small patient sample size and were not randomized, controlled studies.

Emons et al. randomized 135 patients with advanced ovarian cancer to receive the GnRH triptorelin or placebo, following surgery and chemotherapy, until the patient's death or termination of the trial. There were no significant differences in OS or PFS between the groups, with documented gonadotropin suppression (286).

At least four randomized studies comparing chemotherapy and MPA or a GnRH versus chemotherapy alone in ovarian cancer patients have been reported. These studies contain many of the same flaws as noted throughout this discussion, namely, small sample size and no stratification for optimal versus suboptimal surgical status, menopausal status, and histologic status.

Argenta et al. evaluated fulvestrant in women with recurrent ovarian or primary peritoneal cancer. Thirty-one women were enrolled, and 26 women (median age, 61 years) met inclusion criteria and received at least one dose. Patients had received a median of five prior chemotherapeutic regimens (range, 2–13). One CR (4%), one PR (4%), and 9 patients with SD (35%) were observed, using response evaluation criteria in solid tumors (RECIST) (CA-125 level). Using modified-RECIST criteria, 13 patients (50%) achieved SD. The median time to disease progression was 62 days (mean, 86 days). Grade I toxicity included headache (1 patient) and bromhidrosis (2 patients). Fulvestrant was well-tolerated and efficacious. Objective response rates were low, but disease stabilization was common (287).

Smyth et al. in a phase II study of letrozole evaluated the efficacy of this aromatase inhibitor in preselected ER positive relapsed epithelial ovarian cancer patients (288). The primary end-point was response according to CA-125 and RECIST. Marker expression was measured by semiquantitative immunohistochemistry in sections from the primary tumor. Of 42 patients evaluable for CA-125 response, 7 (17%) had a response (decrease of >50%), and 11 (26%) patients had not progressed (doubling of CA-125) following 6 months of treatment. The median time taken to achieve the CA-125 nadir was

13 weeks (range, 10–36). Of 33 patients evaluable for radiological response, 3 (9%) had a partial remission, and 14 (42%) had stable disease at 12 weeks. Eleven patients (26%) had a PFS of > 6 months. This is the first study of a hormonal agent in a pre-selected group of ER-positive ovarian cancer patients. Further studies must be undertaken.

As previously stated, in patients with ovarian cancer, receptor status does not reproducibly correlate with prognostic factors, including survival or disease-free interval. However, receptor status may be useful in predicting response to hormonal agents. Although several investigators have approached this question, results are inconclusive. The ascertainment of receptor status as a predictor of hormonal activity in ovarian cancer will require a randomized clinical trial comparing hormonal activity in patients expressing hormone receptors versus those with no receptor expression, controlling for the many variables recognized as important prognosticators in ovarian cancer.

Colon

The clinical data available evaluating the relationship between hormones and colon cancer relate primarily to hormones as risk factors for the development of this common human malignancy. There is a plethora of data in colon cancer cell lines regarding the effect of hormonal agents on cell growth, as well as cell death. To date, there are no clinical studies evaluating the treatment of colon cancer, either in the adjuvant setting or otherwise, with hormonal agents.

Clinical Trials Methodology and Biostatistics

MARK F. BRADY ■ JEFFREY C. MIECZNIKOWSKI ■
VIRGINIA L. FILIACI

Issues involved in the design, conduct, and analyses of clinical trials are presented in this chapter. Phase 1, 2, and 3 trials are presented, as well as screening trials. Statistical jargon and mathematical notation are avoided wherever possible. Studies from the field of gynecologic oncology are used as examples in order to illustrate specific points. This chapter is an overview of these very expansive topics. Details concerning the design, conduct, and analysis of clinical trials can be found in books dedicated to this subject, such as Piantadosi (2005) (1), Green et al. (2003) (2).

This chapter begins with some historical snippets in order to provide a sense of how the concepts of clinical trials evolved and matured from an intuition-based practice of medicine to the more sophisticated evidence-based medicine used today. The procedures for designing, conducting, and analyzing clinical trials continue to mature as the demand for evidence-based medicine increases. Next, a general system of classifying study designs is presented. The subsequent sections in this chapter describe the components of a clinical trial and essential considerations for developing new trials. Since translational research objectives are incorporated into many modern cancer trials, some issues related to design and analyses of these components are also considered.

HISTORICAL PERSPECTIVE

Clinicians make treatment recommendations daily. These recommendations arise from culling information from standardized clinical guidelines, published reports, expert opinion, or personal experiences. The synthesis of information from these sources into a particular recommendation for an individual patient is based on a clinician's personal judgment. But what constitutes reliable and valid information worthy of consideration? Clinicians have long recognized that properly planned and conducted clinical trials are important sources of empirical evidence for shaping clinical judgment.

The Greek physician Hippocrates in the 5th century BCE had a profound influence in freeing medicine from superstition. He rejected the notion that the cause of an individual's disease had a divine origin. Rather, he postulated that diseases originated from natural causes that could be determined from observing environmental factors like diet, drinking water, or local weather. He also proposed the revolutionary concept that a physician could anticipate the course of a disease after carefully observing

a sufficient number of cases. Despite these insights, medicine all too frequently continued to consist of a mixture of herbal concoctions, purging, bloodletting, and astrology.

In the Middle Ages, Avicenna (980–1037 CE) wrote *Canon of Medicine*, a work considered to be the pre-eminent source of medical and pharmaceutical knowledge of its time. In his writings Avicenna proposed some rules for testing clinical interventions. First, he pointed to the need to experiment in humans, since “testing a drug on a lion or horse might not prove anything about its effect on man.” Also, he described the basic experiment as observing pairs of individuals with uncomplicated but similar forms of the disease. Finally, he emphasized the need for careful observation of the times of an intervention and then reporting the reproducibility of its effects (3). Despite these insights, his *Canon of Medicine* does not include any specific reports of clinical experimentation.

Early trials frequently lacked concurrent comparison groups. For example, Lady Mary Wortley-Montague in 1721 urged King George I to commute the sentences of 6 inmates from the Newgate prison if they agreed to participate in a smallpox inoculation trial (3). The prisoners were inoculated with smallpox matter from a patient with a naturally occurring form of the disease. Since these individuals remained free of smallpox, this finding was considered to be evidence supporting treatment by inoculation. Later, however, the results of this trial were considered less compelling, when it was discovered that some of the inmates might have been exposed to smallpox prior to the trial (4). Without a proper control group, it can be difficult to interpret the efficacy of an intervention. There are frequently many factors, both known and unknown, that influence an individual's outcome.

Subjective assessments from either the subject or the practitioner may also influence the interpretability of a trial. In the late 18th century, the King of France selected Benjamin Franklin to head a royal commission to investigate the physician Franz Mesmer's claims that he could promote good health by manipulating a force he called “animal magnetism” (5). Franklin devised several ingenious experiments in which the subjects were blindfolded and not told whether or not they were receiving Mesmer's treatment. These trials led Franklin to conclude that the therapeutic effects of mesmerism were due to imagination and illusion. Several years later, John Haygarth demonstrated the importance of controlling for assessment biases. At that time, magnetic healing rods were commonly used to relieve pain due to chronic rheumatism (4). Haygarth treated 5 patients on 2 consecutive days, once with sham wooden rods and once with genuine magnetic rods. He noted that 4 individuals reported pain relief and 1 experienced no relief, regardless of which rods were used. Franklin's and Haygarth's trials established the importance of implementing experimental procedures aimed at removing subjectivity from the assessment of treatment effects.

Alan D. Hutson, PhD, and Brian N. Bundy, PhD, contributed to prior editions of this chapter

It had long been appreciated that there is a potential for misguided inference about the effectiveness of a treatment when the comparison involves a group with a dissimilar prognosis. The apparent benefits attributed to a new treatment might in fact be biases due to prognostic differences in patients between treatment groups. One of the earliest clinical trials to attempt to address this bias was reported in 1898 by Johannes Fibiger (6). Four hundred and eighty-four patients admitted to his clinic with diphtheria were given either standard care or diphtheria serum twice daily. In order to disassociate the mode of treatment from the individual's prognosis, the patient's treatment was to be determined by the day of clinic admission, and it alternated from day to day (7). Using this type of procedure to disassociate prognosis from treatment is only partially effective, since the practitioner or the subject knew which treatment would be applied, and this knowledge may have influenced the individual's decision to participate in the study. Therefore, masking the treatment assignment so that it cannot be part of the decision to participate in the trial is important for controlling this source of selection bias.

Treatment randomization in agricultural trials was performed as early as 1926 (8). However, it was not until the 1940s when Corwin Hinshaw (9), using a coin toss, and later Bradford Hill (10), using random numbers in sealed envelopes, established the methodologic importance of randomizing treatments in clinical trials. Balancing the unpredictable and spontaneous remissions exhibited by some patients with pulmonary tuberculosis motivated Amberson (8) and later Hinshaw (9). While methodologic principles motivated Hill, the short supply of streptomycin after World War II provided the opportunity to use randomization as an equitable way to distribute the drug (11).

One of the first randomized clinical trials in the study of gynecologic malignancies was initiated in 1948 (12). This trial compared ovarian irradiation to standard treatment for breast cancer. Initially, shuffled sealed envelopes were used to designate treatment. However, this procedure was later changed due to administrative difficulties so that treatment depended on the woman's date of birth. This later procedure is susceptible to the same selection bias mentioned in Fibiger's trials, since the treatments were not masked.

Despite these methodological advances, the inadequate justification for selecting one medical procedure over another led one contemporary physician to express his frustration:

Early in my medical career I was appalled at the 'willy-nilly' fashion by which treatment regimens slipped in and out of popularity. How many operations that I was trained to do or medicines that I was instructed to give because of somebody's conviction they were beneficial passed into oblivion for no apparent reason, only to be replaced by others of equally dubious worth? (13)

The first randomized clinical trial at the National Cancer Institute (NCI) was begun in 1955 (14). This trial involved 65 evaluable patients with acute leukemia from 4 different institutions. The trial incorporated many elements that should be part of any modern clinical trial: uniform criteria for response assessment, a randomized comparison of at least 2 treatment regimens, and a complete accounting of all patients entered. The published report included considerations for such issues as patient selection bias and the study's impact on the patient's welfare (15). The first NCI randomized clinical trial in solid tumors followed shortly thereafter and was organized by the Eastern Group for Solid Tumor Chemotherapy (16). By 2010, there were 12 NCI-sponsored cooperative groups conducting clinical trials and the annual funding for these groups was \$163 million dollars (17).

In the late 1950s, most patients with gynecologic cancers were included incidentally in small trials to screen new agents for broad-range activity. The first NCI-sponsored group to organize

trials specifically for gynecologic malignancies was the Surgical Ovarian Adjuvant Group. This group was formed in the late 1950s, initiated a few trials, and then disbanded in 1964. Starting in 1963, the Surgical Endometrial Adjuvant Group was one of the earliest efforts toward a multidisciplinary group. This multidisciplinary cooperative group included gynecologic surgeons, medical oncologists, pathologists, radiation oncologists, and biostatisticians. It was from this group that the Gynecologic Oncology Group (GOG) was eventually formed in 1970 to deal with a broader range of gynecologic malignancies (18). Over the following 10 years, the field of gynecologic oncology matured. Board certification procedures for gynecologic oncologists were developed, fellowship programs were initiated in the comprehensive cancer centers, and a professional Society of Gynecologic Oncologists was organized in 1969.

Classification of Study Designs

In general, a clinical trial is any experiment involving human subjects that evaluates an intervention that attempts to reduce the impact of a specific disease in a particular population. When an intervention is applied in order to prevent the onset of a particular disease, the trial is classified as a primary prevention trial. For example, a primary prevention trial may evaluate healthy lifestyles or a vitamin supplement in a population of individuals who are considered to be at risk for a particular disease. Secondary prevention trials evaluate interventions that are applied to individuals with early stages of a disease in order to reduce their risk of progressing to more advanced stages of the disease. Tertiary intervention trials are aimed at evaluating interventions that reduce the risk of morbidity or mortality due to a particular disease.

Clinical trials that evaluate methods for detecting a disease in a preclinical state are called screening trials. Early detection may mean diagnosing a malignancy in an early stage (e.g., the use of mammography in the detection of breast cancer) or in a premalignant state (e.g., the use of Papanicolaou smear in the detection of cervical intraepithelial neoplasia). There are typically 2 interventions in a screening trial. The first intervention is the screening program (e.g., annual mammograms), which involves individuals who appear to be free of the disease. However, once the disease is detected in an individual, a secondary intervention (e.g., surgery) is performed in hopes of stopping the disease from progressing to more advanced stages. Consequently, screening trials require *both* interventions to be effective. An effective screening procedure is useless if the secondary intervention does not alter the course of the disease. On the other hand, an ineffective screening procedure would cause the secondary intervention to be applied indiscriminately.

Nonexperimental studies (or observational studies) can be classified into 3 broad design categories: cohort (or prospective), case-control (or retrospective), and cross-sectional. In a cohort study, individuals are initially identified according to their exposure status, which can include environmental, genetic, lifestyle, or therapeutic treatment factors. These individuals are then followed in order to determine who develops the disease. The aim of these studies is to assess whether the exposure is associated with the incidence of the disease under study. This design is in contrast to the case-control study, which identifies individuals on the basis of whether they have the disease and then measures and compares their exposure histories. Measuring exposure may be as simple as questioning the individuals about their personal or employment history, or it may involve a more sophisticated assessment such as analyzing the individual's biologic specimens for markers of exposure. Though the case-control study is susceptible to several methodological flaws, it has the advantage of often being less expensive, easier, and quicker to perform than a cohort study, especially when the disease is rare. The power of the case-control design is apparent

from a review of the case-control studies published between 1975 and 1985(19), which demonstrated the deleterious effects of exogenous estrogens in perimenopausal women. Finally, the goal of the cross-sectional study is to describe the prevalence of a disease and an exposure in a population during a specific period of time. These studies can often be conducted more quickly than either the cohort or case-control study, but they are often not used when the time between exposures and the disease onset is long, as it is for cancer.

Components of a Clinical Trial

Objectives

In clinical oncology research, where the disease is often fatal, the ultimate purpose of a research program is to develop a treatment plan that puts the patients into a disease-free state, reduces the risk of cancer recurrence, and allows patients to return to their normal lifestyle within a reasonable period of time. The objectives of a particular clinical trial are often more specific and less grandiose. A clinical trial attempts to answer a precisely defined set of questions with respect to the effects of a particular treatment(s) (20). These questions (objectives) form the foundation upon which the rest of the trial is built. The study objective typically incorporates 3 elements: the interventions to be evaluated, the “yardstick” to be used to measure treatment benefit (see Endpoints), and a brief description of the target population (see Eligibility Criteria). These 3 elements (i.e., “what,” “how,” and “who”) should be stated in the most precise, clear, and concise terms possible.

The choice of experimental therapy to be evaluated in a randomized clinical trial is not always easy. Both a plethora of new therapies and the absence of innovative concepts make for difficult choices. The former is problematic since many malignancies in gynecologic oncology are relatively uncommon. Definitive clinical trials may require 4 to 5 years to accrue a sufficient number of patients even in a cooperative group setting. This time-frame limits the number of new therapies that can be evaluated. The absence of new therapies is a problem since substantial increases in patient benefit are less likely to be observed in trials that merely alter doses or schedules of already acceptable therapies. An open dialogue among expert investigators remains the most effective approach for establishing the objectives of any clinical trial.

Endpoints

The endpoint of a trial is some measurable entity in the patient’s disease process that can be used to assess the effectiveness of an intervention. A study may assess more than 1 endpoint, but in these instances the endpoint of primary interest should be clearly specified or else the study design should carefully reflect the complexity of interpreting multiple outcomes. Endpoints can be a composite measure of multiple outcomes. For instance, some studies assessing quality of life aggregate patient reported scores from several related items or domains that are all considered components of a larger concept called quality of life.

Selecting endpoints that will reflect the effectiveness of an experimental therapy is not always obvious. First, endpoints should be a valid (unbiased) measure of the treatment effect on the disease process. Endpoints that are susceptible to a systematic error that favors one treatment lead to biased estimates of the treatment’s effect. For instance, trials assessing time to disease progression, in which the schedule for CT scans is different for each treatment group, are susceptible to this assessment bias. This problem is not uncommon in studies comparing two different modalities such as chemotherapy and radiation therapy. Second, the measurement of an endpoint should be reliable and not

susceptible to subjective interpretation. In some cases clinical response can be considered unreliable, since it is not uncommon for experts to disagree when interpreting the same radiograms (21). Third, endpoints that are directly relevant to the patient are preferable, although valid surrogate endpoints are considered indirectly relevant to the patient. Finally, endpoints which are not too expensive or inconvenient for the patient are preferred. It is not always possible for a single endpoint to exhibit all of these characteristics simultaneously. For example, avoiding death is extremely relevant to a patient with a lethal disease like advanced gynecologic cancer. Also, survival can be measured very reliably. However, most cancer patients will not only receive the treatments prescribed by the study, but, after exhibiting signs of disease progression, they also receive other anticancer therapies. In this case, the validity of overall survival comparisons is suspected since they not only reflect the effects of the study treatment, but also the effects of other therapies that are external to the study. For example, a meta-analysis of those trials comparing the survival of patients, who were randomized to nonplatinum versus platinum regimens for the treatment of advanced ovarian cancer, concluded that these trials appear to have underestimated the true effect of platinum on survival. The reason is that many patients who were not randomized to the platinum regimen eventually received platinum treatment (22). For this reason, progression-free survival (PFS) is often considered a reasonable endpoint in those trials, since it is unaffected by subsequent therapies (23). Nevertheless, some authors have argued that survival remains an important endpoint to be assessed in Phase III trials, even when active second-line treatments are available (24). Moreover, overall survival remains the recommended preferred endpoint in trials that explicitly compare a strategy of immediate treatment versus delayed treatment for advanced stage disease.

Endpoints may be classified as categorical (e.g., clinical response), continuous (e.g., serum CA-125 values) or time-to-event (e.g., survival time). A time-to-event endpoint includes both time (a continuous measure) and censoring status (categorical measure). The data type influences the methods of analysis.

Measurement Errors

The susceptibility of an outcome to measurement errors is an important consideration when choosing an endpoint. Both random and systematic errors are components of measurement error. Random error refers to that part of the variation that occurs among measurements that is not predictable, and appears to be due to chance alone. For example, a serum sample could be divided into 10 aliquots and submitted to the laboratory for CA-125 determinations. If the laboratory returns nearly the same value for each aliquot, then the associated random error is low, and the measurement may be deemed reproducible. On the other hand, if the CA-125 values vary considerably among aliquots, perhaps due to inconsistent laboratory procedures, then individual values may be considered unreliable. In this case, taking the average CA-125 measurement across all 10 aliquots is expected to be a better estimate of the patient’s true CA-125 value than any single measurement.

Concern for reliability is one of the reasons for incorporating several items into a quality of life questionnaire. Quality of life is a complex entity and no single question can be expected to reliably measure it. A measurement of an individual’s quality of life is therefore typically composed from an individual’s responses to several items that are all considered to be associated with quality of life. Indeed, one step toward demonstrating the usefulness of any quality of life instrument is to show that it provides reproducible results when assessing individuals under the same conditions (25).

Systematic error, also called bias, refers to deviations from the true value that occur in a systematic fashion. For example,

suppose an investigator initiates a randomized clinical trial comparing two treatments with time to disease progression being the primary endpoint. The protocol indicates that the patient should be assessed after each cycle of therapy. However, suppose that a cycle duration is 2 weeks for one treatment group, and 4 weeks for the other treatment group. Using a more intense assessment schedule for 1 treatment group would tend to detect failures earlier in that group. Therefore, the time-to-failure comparison between treatments would systematically favor the second treatment group.

When there are recognized sources of error, it is important that the study design implement procedures to avoid or minimize their effect. For example, random error in many cases can be accommodated by either increasing the number of individuals in the study, or in some cases by increasing the number of assessments performed on each individual. Systematic measurement error cannot be addressed by increasing the sample size. In fact, increasing the sample size may exacerbate the problem since small systematic errors in large comparative trials contribute to the chances of erroneously concluding that the treatment effect is “significant.” The approaches to controlling sources of systematic error tend to be procedural. For example, treatment randomization is used to control selection bias, placebos are used to control observer bias, standardized assessment procedures and schedules are used to control measurement bias, and stratified analyses are used to control biases due to confounding. For an extensive description of biases that can occur in analytic research see Sackett, 1979 (26).

Surrogate Endpoints

Surrogate endpoints do not necessarily have direct clinical relevance to the patient. Instead, surrogate endpoints are intermediate events in the etiologic pathway to other events that are directly relevant to the patient (27). The degree to which a treatment’s effect on a surrogate endpoint predicts the treatment’s effect on a clinically relevant endpoint is a measure of the surrogate’s validity. The ideal surrogate endpoint is an observable event that is a necessary and sufficient precursor in the causal pathway to a clinically relevant event. Additionally, the treatment’s ability to alter the surrogate endpoint must be directly related to its impact on the true endpoint. It is important that the validity and reliability of a surrogate endpoint be established with appropriate analyses and not simply presupposed (28,29). Surrogate endpoints are sometimes justified on the basis of an analysis that demonstrates a statistical correlation between the surrogate event and a true endpoint. However, while such a correlation is a necessary condition, it is not a sufficient condition to justify using a particular surrogate as an endpoint in a clinical trial. For example, CA-125 levels following 3 cycles of treatment of ovarian cancer have been shown to be associated with the subsequent overall survival (30). Women with newly diagnosed ovarian cancer whose serum CA-125 levels normalize at the end of 3 cycles of standard treatment tend to survive longer than those who have abnormal levels. However, it has not (yet) been demonstrated that the degree to which any particular treatment reduces CA-125 levels reliably predicts its effects on clinically relevant endpoints, like overall survival.

The most frequently cited reasons for incorporating surrogate endpoints into a study include reduction in study size and duration, decreased expense, and convenience.

Primary Endpoints in Gynecologic Oncology Treatment Trials

The Food and Drug Administration (FDA) organized a conference to consider endpoints for trials involving women diagnosed with advanced ovarian cancer (31). Meta-analyses were presented, which indicate that PFS can be considered a valid

endpoint for trials involving women with advanced ovarian cancer. It is important to recognize that while the general validity of PFS for predicting overall survival in this patient population has been established, PFS comparisons in a particular study can be biased. One source of bias arises from using different disease assessment schedules for each treatment group either intentionally or unintentionally. Delaying assessments for 1 treatment group artificially increases the apparent time to progression. Survival time is generally not susceptible to this source of bias.

Progression-free interval (PFI) may be a reasonable endpoint in trials involving patients with early or locally advanced cancer. PFI should be distinguished from PFS. The difference resides in how patients, who die without any evidence of disease progression are handled in the analysis. Patients who die without evidence of progression are censored at the time of their death in a PFI analysis, but considered an uncensored event in a PFS analysis. If deaths due to non-cancer-related causes are common, then selecting PFI as the study endpoint will generally increase the study’s sensitivity for detecting active treatments. In this case, however, the analysis needs to consider procedures that will account for treatment-related deaths, which may occur prior to disease recurrence. Simply censoring the time to recurrence in these cases can make very toxic treatments appear more effective than they actually are.

There have been a number of studies that provided evidence that a new treatment increases the duration of PFS, but not overall survival. For example, OVAR 2.2, a second-line treatment trial involving patients with platinum-sensitive ovarian cancer, indicated that carboplatin and gemcitabine significantly decreased the hazard of first progression or death (PFS) 28% (hazard ratio = 0.72, $p = 0.003$) when compared to carboplatin alone (32). However, there was no appreciable difference between the treatment groups with regard to the duration of overall survival (hazard ratio = 0.96, $p = 0.735$). Also, 3 trials evaluating maintenance bevacizumab for first- and second-line treatment of ovarian cancer reported significant prolongation in the duration of PFS (33–35), but no difference in overall survival. Therefore, while PFS may be a good surrogate for overall survival, it appears to be susceptible to a small but not insignificant chance of false-positive prediction. It is noteworthy, however, that results from PFS seldom lead to false-negative predictions. In other words, it is very rare for the results of an oncology trial to indicate that a new treatment prolongs overall survival but does not delay the onset of recurrence or progression. It seems reasonable to expect that an anticancer treatment that prolongs survival should exert its influence by delaying the onset of new or increasing disease. This has prompted some investigators to recommend using both PFS and overall survival as trial endpoints (36–38). Specifically, trials involving patients with advanced-stage cancer are designed to assess overall survival in the final analysis, but PFS is monitored at scheduled interim analyses. If the trial’s evolving evidence indicates that there is insufficient PFS benefit, then the trial may be stopped early and concluded that the treatment has insufficient activity to warrant further investigation in the target population. This procedure tends to halt trials of inactive treatments early, but continues trials of active agents to completion.

Response (disease status) assessed via reassessment laparotomy following treatment has been proposed for use as a study endpoint in ovarian cancer trials (39). The justification is that patients with no pathologic evidence of disease are more likely to experience longer survival than those with evidence of disease. The principal drawback to this endpoint is that reassessment laparotomy is a very onerous procedure for the patient, and many patients refuse reassessment surgery, or the surgery may become medically contraindicated. Even among highly motivated and very persuasive investigators the percent of patients not reassessed is typically greater than 15%. These missing evaluations can significantly undermine the interpretability of a study.

To date, PFS has not been formally validated for use in trials involving patients with advanced cervical, endometrial, or vulvar cancers. In the absence of a formally validated endpoint, overall survival or symptom relief are reasonable endpoints. Since relief from symptoms is susceptible to assessment bias, trials utilizing this endpoint should use validated instruments (See Measurement Errors) and consider blinding the study treatments whenever possible.

The endpoint selection for trials involving patients with recurrent cervical cancer has been controversial. Historically, some trials have been designed with clinical response as the primary endpoint. However, survival is a preferable primary endpoint. The rationale for this choice arises from the observation that treatments that have demonstrated an improvement in the frequency of response have not consistently prolonged survival (40–42). While subsequent therapies may have distorted the cause-effect relationship, the effect is probably at best minimal since there are no known treatments that have consistently demonstrated an ability to influence the survival time of patients with advanced or recurrent cervical cancer.

In summary, the ideal endpoint provides reasonable assurance that inference about the causal relationship between the intervention and the endpoint is valid. It is either itself clinically relevant to the patient, or predictive of a clinically relevant outcome. The ideal endpoint can be measured reliably. It should be convenient and cost-effective to measure. Unfortunately, in some trials, these features are not always available simultaneously. If a surrogate endpoint is used, then its validity should be established, not presumed.

Eligibility Criteria

The eligibility criteria serve 2 purposes in a clinical trial. The immediate purpose is to define those patients with a particular disease, clinical history, and personal and medical characteristics that may be considered for enrollment in the clinical trial. The subsequent purpose of eligibility criteria comes after the clinical trial is completed and the results are available. Physicians must then decide whether the trial results are applicable to their particular patient. A physician may consider the trial results to be applicable when the patient meets the eligibility criteria of the published study. Unfortunately, this principle is problematic. The necessary sampling procedure for selecting patients for the study (i.e., a random sample of all eligible patients) is never actually applied in clinical trials. Therefore, extrapolation of study results becomes an inherent part of medical practice.

Within the general population, there is a target population that includes those patients for whom the results of the trial are intended to apply (e.g., advanced endometrial cancer with no prior systemic cytotoxic therapies). While an investigator can typically specify an idealized definition for the target population, additional practical issues also frequently need to be considered. For example, there are varying opinions about whether patients diagnosed with an adenocarcinoma of the fallopian tube or primary peritoneal cancer in studies which target the treatment of patients with adenocarcinomas of the ovary. Some clinical investigators will argue for the need to study a “pure” study population and ignore the fact that their treatment decisions for patients with cancers originating in the fallopian tube or peritoneum frequently come from the results of trials involving patients with advanced ovarian cancer. Ideally, the size of a subgroup represented in a study should be in proportion to their presence in the target population. The degree to which a study sample reflects the target population determines the generalizability or external validity of the study results. Eligibility criteria should reflect a concern for the generalizability of the trial results. When clinicians frequently resort to extrapolating the results of a trial to patient groups that were not eligible for the trial, this may be considered a serious indictment of the study’s eligibility criteria.

The ideal situation is when every patient who meets the eligibility criteria of a clinical trial is asked to participate. This is seldom possible since not all physicians, who treat such patients, participate in the study. Also, not all patients wish to be involved in a clinical trial. Impediments in traveling to a participating treatment center further reduce the target population. The source population is the subset of patients in the target population who have access to the study. Figure 17.1 displays common restrictions that can limit the entry of patients to a clinical trial.

Restricted access to the study may contribute a biased sample from the target population, referred to as selection bias. For example, participating investigators at university hospitals might tend to enroll disproportionately more patients with cancer who have undergone very aggressive initial cytoreductive surgeries than their counterparts at community hospitals.

A potentially useful approach for determining the necessity of a particular eligibility criterion is to clearly identify its function. In addition to defining the target population, there are 4 distinct functions that an eligibility criterion may serve: benefit-morbidity equipoise (safety), homogeneity of benefit (scientific), logistic, and regulatory (43).

Eligibility criteria for safety are frequently imposed to eliminate patients for whom the risk of adverse effects from treatment is not commensurate with the potential for benefit. This concern can manifest in two ways. First, in oncology trials, there is often some concern that study treatments may be too toxic for patients with compromised bone-marrow reserves or kidney function. These patients are frequently excluded from trials when the potential benefits of treatment are not consistent with the risk associated with treatment. Second, even otherwise healthy cancer patients may be eliminated from the study when the risks from treatment are considered too great. For example, chemotherapy after hysterectomy is normally considered excessive treatment for a patient with Stage IA cervical cancer, since even without this treatment the risk of relapse is relatively small, but the morbidity of this combined modality following hysterectomy may be substantial. Therefore, eligibility criteria that eliminate these patients can be justified.

Eligibility criteria may be warranted when there is a scientific or biologic rationale for a variation in treatment benefit across patient subgroups. There is no scientific reason to expect that the effect of treatment is entirely the same across all subgroups of patients included in the study. The effect of a new therapy may be expected to have such dramatic inconsistencies across the entire spectrum of the target population that statistical power is compromised (43). One example of this type of exclusion criterion is found in GOG Protocol 152 (A Phase 3 Randomized Study of Cisplatin [NSC#119875] and Taxol [Paclitaxel] [NSC#125973] with Interval Secondary Cytoreduction versus

FIGURE 17.1. Sequential reduction of patient population.

Cisplatin and Paclitaxel in Patients with Suboptimal Stage III & IV Epithelial Ovarian Carcinoma). This study was designed to assess the value of secondary cytoreductive surgery in patients with Stage III ovarian cancer. All patients who entered into this study were to receive 3 courses of cisplatin and paclitaxel. After completing this therapy they were then randomized to either 3 additional courses of chemotherapy or interval secondary cytoreductive surgery followed by 3 additional courses of chemotherapy. The eligibility criteria exclude those patients who had only microscopic residual disease following their primary cytoreductive surgery since there is no scientific reason to expect that interval cytoreduction would be of any value to patients with no gross residual disease.

Clinical investigators frequently implement eligibility criteria in order to promote homogeneity in patient prognoses. The desire to attain a study population with homogeneous prognoses is a common reason for excessive eligibility criteria. However, the concept is both unattainable and overemphasized. This notion may arise from an investigator's attempt to duplicate the experimental method conducted in the laboratory. It is standard practice in laboratory experiments on animals to use inbred strains in an effort to control genetic variability. In large-scale clinical trials, this approach seldom has merit in light of the cost to generalizability. Eligibility criteria should be as broad as possible in order to enhance generalizability. For example, GOG Protocol 165 (A Randomized Comparison of Radiation Plus Weekly Cisplatin versus Radiation plus PVI [Protracted Venous Infusion] 5-FU in Patients with Stage II-B, III-B and IV-A Carcinoma of the Cervix) includes patients with no surgical sampling of the paraaortic lymph nodes. Previous GOG trials required sampling of these nodes. However, there is no evidence or sound biological justification to support the notion that the relative treatment benefit depends on the extent of surgical staging. This is not to say whether or not surgical staging is itself beneficial.

Eligibility criteria can be justified on the basis of logistic considerations. For example, a study that requires frequent clinic visits for proper evaluation or toxicity monitoring may restrict patients who are unable to arrange reliable transportation. The potential problem with such a restriction is how it is structured. A criterion requiring that the patient have a car at her disposal is probably too restrictive in a trial of women with advanced cervical cancer, since patients from this target population tend toward poorer socio-economic status (SES) and may not have access to private transportation. Such a restriction erodes the generalizability of the trial by over sampling patients with higher SES and may prolong study accrual. Moreover, complicated eligibility criteria are more likely to function ineffectively. In general complicated eligibility restrictions should be avoided.

Eligibility criteria based on regulatory considerations include institutional and governmental regulations that require a signed and witnessed informed consent and study approval by the local Institutional Review Board. These restrictions are required in most research settings and are not subject to the investigator's discretion.

Currently many biostatisticians believe that eligibility criteria in oncology trials tend to be too restrictive and complicated (43,44). Overly restrictive or complex eligibility criteria hamper accrual, prolong the study's duration, and delay the reporting of results. The Medical Research Council has demonstrated that it is possible to conduct trials with simple and few eligibility criteria (45). The ICON3 (International Collaborative Ovarian Neoplasms) trial compares standard carboplatin or cisplatin adriamycin cyclophosphamide regimen with paclitaxel plus carboplatin in women with newly diagnosed ovarian cancer. This trial has 6 eligibility criteria, 3 of which are for safety: (a) fit to receive, and no clear contraindication to, chemotherapy, (b) Absence of sepsis, and (c) bilirubin less than twice the normal level for the center. This is in sharp contrast to GOG Protocol 162 (A Phase 3 Randomized Trial of Cisplatin [NSC #119875]

with Paclitaxel [NSC #125973] Administered by Either 24-Hour Infusion or 96-Hour Infusion in Patients with Selected Stage III and Stage IV Epithelial Ovarian Cancer), which compares 2 different paclitaxel infusion durations in patients with advanced ovarian cancer and has 34 eligibility criteria.

Phases of Drug Development trials

The traditional approach to identifying and evaluating new drugs has relied on sequential evidence from Phase 1, 2, and 3 clinical trials. Each of these study designs stems from very distinct study objectives. Phase 2 trials build on the evidence gathered from Phase 1 trial results, and similarly Phase 3 trials build on Phase 2 and Phase 1 trial results. The investigation of a given treatment may be halted at any phase, either due to safety and/or efficacy issues. Depending upon the underlying investigation, the time from the initiation of a Phase 1 trial for a given treatment to the completion of a Phase 3 trial often spans several years.

Phase 1 Trials

The purpose of a Phase 1 therapeutic trial in cancer-related research is to determine an acceptable dose or schedule for a new therapy as determined by toxicity and/or pharmacokinetics. A Phase 1 trial marks the first use of a new experimental agent in humans. Most Phase 1 trials escalate the dose or schedule of the new agent after either a pre-specified number of consecutive patients has been successfully treated or within an individual as each dose is determined to be tolerable. The usual Phase 1 trial of a cytotoxic agent attempts to balance the delivery of the greatest dose intensity against an acceptable risk of dose limiting-toxicity (DLT). The conventional approach increases the dose after demonstrating that a small cohort of consecutive patients (3 to 6) is able to tolerate the regimen. However, once an unacceptable level of toxicity occurs (e.g., two or 3 patients experiencing DLT), the previously acceptable dose level is used to treat a few additional patients in order to provide additional evidence that the current dose has an acceptably low risk of DLT. If this dose is still regarded as acceptable, it becomes the dose and schedule studied in subsequent trials and it is referred to as the recommended dose level (RDL). The RDL should not be confused with the maximum tolerated dose (MTD). The MTD is a theoretical concept used to design a Phase 1 trials, while the RDL is an *estimate* of the MTD, which may or may not be accurate. Due to the limited number of patients involved in a Phase 1 trials outcome measures such as response and survival are not the primary interest in these studies. When these outcomes are reported, they are considered anecdotal evidence of treatment activity. Eligibility criteria for Phase 1 trials in oncology often limit accrual to patients in whom conventional treatments have failed.

Alternative strategies for estimating the MTD have been proposed. The primary motivation for these newer strategies is to reduce the number of patients treated at therapeutically inferior doses and to reduce the overall size of the study. One of these alternatives implements a Bayesian approach and is referred to as the continual reassessment method (CRM) (46). It has the attractive feature of determining the dose level for the next patient based on statistically modeling the toxicity experience of the previously treated patients. While the traditional approach has been criticized for treating too many patients at subtherapeutic doses and providing unreliable estimates of the MTD, CRM has been criticized for tending to treat too many patients at doses higher than the MTD (47). Refinements to CRM have been proposed (48) and found to have good properties when compared to alternative dose-seeking strategies (49). Another family of designs termed the accelerated titration design (ATD) allows doses to be escalated within each patient and incorporates toxicity or

pharmacologic information from each course of therapy into the decision of whether to further escalate or not (50). Both the modified CRM and ATD designs can provide significant advantages over the conventional Phase 1 design.

Special Phase I study designs are often recommended for targeted agents. These studies will often incorporate a biomarker endpoint that signals either the activation or deactivation of a targeted pathway. As the dose is increased for small cohorts of individuals, the biomarker is measured and toxicity is monitored simultaneously. Then, statistical models are used to determine a safe dose where the targeted pathway is consistently activated or inhibited (51).

Even though the majority of Phase 1 trials in cancer research follow what was described above, it should be mentioned that alternative Phase 1 trials may arise in other settings such as medical device trials, prevention trials, education intervention trials, and behavior modification trials, where the first phase of investigation may actually utilize healthy subjects, such as studies interested in determining the utility of a new educational intervention on smoking cessation. The Phase 1 trial may simply be utilized as an approach towards gaining some experience with the intervention prior to moving forward to the next phase of investigation.

Phase 2 Trials

Once a dose and schedule for a new regimen has been deemed acceptable, a reasonable next step is to seek evidence that the new regimen is worthy of further evaluation in a particular patient population. The principal goal of a Phase 2 trial is to prospectively quantify the potential efficacy of the new therapy. Since a Phase 2 trial treats more patients at the RDL than a Phase 1 trial, it also provides an opportunity to more reliably assess toxicities. A Phase 2 trial is often referred to as a drug-screening trial because it attempts to judiciously identify active agents worthy of further study in much the same way a clinician screens a patient for further evaluation. The study should have adequate sensitivity to detect active treatments and adequate specificity for rejecting inactive treatments. A Phase 2 trial may evaluate a single new regimen, or incorporate randomization to evaluate several new therapies or treatment schedules simultaneously.

There are several concerns that need to be considered when weighing the decision to conduct a single-arm versus a multi-arm randomized Phase 2 study. While the required sample size is smaller for the single-arm trial, this design is susceptible to several sources of biases (52). Single-arm trials often assume that the probability of response to standard treatment in the target population is known with certainty. However, this assumption is often suspect. There are often unanticipated or unknown differences between the study sample and the historical sample which can introduce significant biases into the comparisons. For instance, there may be differences in the patients' prognoses unintentionally introduced by the study's eligibility criteria or changes in patient referral patterns. Differences in the response assessment schedule, the modalities for evaluation, or the definition of response may change over time and therefore distort comparisons with historical results. Generally, randomized controlled Phase 2 studies are preferred over single-arm studies. However, when the probability of response to standard treatment is widely accepted to be very low (e.g., <5%), it may be reasonable to conduct a single-arm studies. Investigators who conduct Phase 2 studies in rare diseases often argue in favor of single-arm designs; however, these are often the cases where the historical data is usually least understood and most susceptible to the previously mentioned biases.

Phase 2 trials can have a single-stage or multistage design. In a single-stage design, a fixed number of patients is treated with the new therapy. The goal of the single-stage design is to achieve a predetermined level of precision in estimating the endpoint.

While precision is one important goal in cancer trials, there is also a concern for reducing the number of patients treated with inferior regimens. For this reason many Phase 2 cancer trials use multistage designs. Multistage designs implement planned interim analyses of the data and apply predetermined rules to assess whether there is sufficient evidence to warrant continuing the trial. These rules, which are established prior to initiating the study, tend to terminate those trials with regimens having less than the desired activity, and tend to continue to full accrual of those trials with regimens having at least a minimally acceptable level of activity. Two-stage designs that minimize the expected sample size when the new treatment has a clinically uninteresting level of activity have been proposed for single-arm studies (53) and multiarm studies (54). In the cooperative group setting, there is often a need for flexibility in specifying exactly when the interim analysis will occur. This is due to the significant administrative and logistic overhead of coordinating the study in several clinics. Therefore, designs that do not require that the interim analyses occur after a precise number of patients is entered, are useful in the multi-institutional setting (55).

Regardless of the measure of treatment efficacy, most designs treat toxicity as merely a secondary observation. This approach is not likely to be appropriate in Phase 2 trials of very aggressive treatments, such as high-dose chemotherapy with bone-marrow support. In these trials, stopping rules that explicitly consider both response and the cumulative incidence of certain toxicities may be more appropriate (56–58). Bayesian designs, which permit continuous monitoring of both toxicity and response, have also been proposed (59).

Phase 3 Trials

The goal of a Phase 3 trial is to prospectively and definitively determine the effects of a new therapy relative to a standard therapy in a well-defined patient population. Phase 3 trials are also used to determine an acceptable standard therapy when there is no prior consensus on the appropriate standard therapy. Some Phase 3 trial methodologies such as randomization and blocking have origins in comparative agricultural experiments. However, in clinical trials the experimental unit is a human being and consequently, there are 2 very important distinctions. First, each individual must be informed of the potential benefits as well as the risks and must freely consent to participate before enrollment in the study. Second, an investigator has very limited control over the patient's environment during the observation period. This later distinction can have a profound statistical implication, which will be discussed later.

Phase 3 Trials with Historical Controls

The strict definition of a Phase 3 trial does not necessitate concurrent controls (i.e., prospectively enrolled patients assigned the standard treatment) or randomization (i.e., random treatment allocation). However, these 2 features are almost synonymous with Phase 3 trials today. The principal drawback from inferring treatment differences from a historically controlled trial is that the treatment groups may differ in a variety of characteristics that are not apparent. Differences in outcome, which are in fact due to differences in characteristics between the groups, may be erroneously attributed to the treatment. While statistical models are often used to adjust for some potential biases, adjustments are possible only for factors that have been recorded accurately and consistently from both samples. Shifts in medical practice over time, differences in the definition of the disease, eligibility criteria, follow-up procedures or recording methods can all contribute to a differential bias. Unlike random error, this type of error cannot be reduced by increasing the sample size. Moreover, the undesirable consequences of moderate biases may be exacerbated with larger sample sizes. When a trial includes *concurrent*

controls, the definition of disease and the eligibility criteria can be applied consistently to both treatment groups. Also, the standard procedures for measuring the endpoint can be uniformly applied to all patients. Inclusion of prospectively treated controls within the clinical trial requires a method of assigning the treatments to patients. Randomization and its benefits are discussed in a later section.

It is useful to distinguish Phase 3 objectives as having an efficacy, equivalency, or noninferiority design consideration. An efficacy design is characterized by the search for an intervention strategy that provides a therapeutic advantage over the current standard of care. An equivalency trial seeks to demonstrate that 2 interventions can be considered sufficiently similar on the basis of outcome that 1 can be reasonably substituted for the other. Noninferiority trials seek to identify new treatments that reduce toxicity, patient inconvenience, or treatment costs without significantly compromising efficacy.

Efficacy trials. Efficacy designs are very common in oncology trials. Examples include: trials that assess the benefit of adding chemotherapy to radiation for the treatment of early-stage cervical cancer or trials that compare standard versus dose intense platinum regimens for treating ovarian cancer. In each of these cases, the trial seeks to augment the standard of care in order to attain a better treatment response. From the outset of these trials it is recognized that the treatment benefit may be accompanied by an increased risk of toxicity, inconvenience, or financial cost. However, it is hoped that the benefits will be sufficiently large to offset these drawbacks. Suppose treatment A is the standard of care for a particular target disease population. The quantitative difference between treatments with respect to a particular outcome ($B-A$) can be described on a horizontal axis as in Figure 17.2. If we are reasonably certain that the difference between treatments is less than 0 (left of 0) then we would consider treatment A to be better. On the other hand, if the treatment difference is greater than 0 (right of 0) then we would conclude that the new treatment, B, is better. Furthermore, we can use dotted lines to demarcate on this graphic a region in which the difference between A and B is small enough to warrant no clinical preference for A or B. Consider the results from a trial expressed as the estimated difference between treatments and the corresponding 95% or 99% confidence interval superimposed on this graph. The confidence interval depicts those

values of the treatment difference that can be reasonably considered consistent with the data from the trial. An inconclusive trial is characterized by having such broad confidence intervals that the data cannot distinguish between A being preferred or B being preferred (see Figure 17.2). This is a typical consequence of a small trial. On the other hand, if the confidence interval entirely excludes the region where A is better than B, then we can conclude that B is significantly better than A (see Fig. 17.2). Note that in this case the lower bound of the confidence interval may extend into the region of clinical indifference, but the confidence interval must exclude the region below (left of) 0 difference.

Equivalency trials. The equivalency study design is perhaps a misnomer, since it is actually impossible to generate enough data from any trial to definitively claim that the 2 treatments are equivalent. Instead, an investigator typically defines the limits for treatment differences that can be interpreted as clinically irrelevant. If it is a matter of opinion for what differences in effect sizes can be considered clinically irrelevant, this issue can become a major source for controversy in the final interpretation of the trial results. Survival or progression-free survival endpoints are seldom used in equivalency trials; however, bio-equivalency designs are sometimes used for drug development. For example, if 1 agent is known to influence a particular biologic marker, then it may be desirable to design a trial to determine whether a new agent is as effective at modifying the expression of this biomarker. In this case, an investigator has some notion about the acceptable range of activity that can be considered clinically biologically equivalent. These studies are designed so that, within tolerable limits, the treatments can be considered equivalent.

Notice that the results from the inconclusive trial in Figure 17.2 cannot be interpreted as demonstrating equivalency. Even though the estimated difference between the treatments is nearly 0, the confidence interval cannot rule out treatment differences that would lead to preferring A or B. Caution should be exercised in interpreting the results from studies that conclude “therapeutic equivalency” when only a small difference between treatments with regard to the outcome is observed and it is declared to be not statistically significant. Even results from moderately large trials, which suggest therapeutic equivalence, may in fact be due to inadequate statistical power to detect clinically relevant differences.

FIGURE 17.2. Graphical representation of the point estimates and confidence intervals describing the results from 4 hypothetical trials.

Noninferiority trials. A noninferiority study design may be considered when the currently accepted standard treatment is associated with significant toxicity and a new and less toxic treatment becomes available. The goal of this type of study is to demonstrate that substituting the new treatment for the current standard treatment does not compromise efficacy appreciably (60–63). Referring to Figure 17.2, the trial seeks to provide sufficient evidence to be reasonably certain that the difference between A and B lies above the lower boundary of the indifference region. This lower boundary is often called the “noninferiority margin.”

The justification for the noninferiority margin selected in a particular study is often controversial. If this margin is set too low, then the study has an unacceptably high probability of recommending an inferior treatment. If it is too high, then the trial utilizes too many clinical and financial resources. In order to select an appropriate margin of noninferiority, it is important to recognize that even though a noninferiority trial may explicitly compare only 2 treatments, implicitly there is a third treatment to be considered. For example, suppose that several historical studies indicate that treatment A is better than a placebo for treating a specific disease. In this case, the goal of a noninferiority study is to demonstrate that a new experimental treatment, B, does not significantly compromise efficacy when compared to currently accepted active standard treatment, A. However, it should also demonstrate that B would have been better than a placebo, if it had been included in the current trial. In other words, the current trial will directly estimate the effectiveness of B relative to A, but it must also indirectly consider the effectiveness of B relative to the previous control treatment (placebo in this case). This indirect comparison relies on obtaining a reliable and unbiased estimate of the effectiveness of the current active control to the previous control from previous trials. Sometimes the margin of noninferiority is expressed as a proportion of the effectiveness of A relative to the previous standard treatment. For example, a noninferiority study could be designed to have a high probability of concluding that a new treatment retains at least 50% of the activity of the standard regimen, A. Note that an investigator may decide that she is unwilling to give up any of the benefit attributed to the current standard treatment. In this case, the margin of noninferiority is set at 0 (see Fig. 17.2) and the design is the same as the efficacy trial. Indeed an efficacy trial can be considered a study in which the investigator is willing to accept the new treatment B, only if the trial results indicate that B is superior to A.

Obtaining reliable estimates for the activity of the currently accepted active standard treatment can be a very troublesome aspect of noninferiority oncology trials. For example, cisplatin 75 mg/m² and paclitaxel 135 mg/m² infused over 24 hours was the first platinum-taxane combination to demonstrate activity in the treatment of advanced ovarian cancer (64). Subsequently, several trials were conducted to assess whether carboplatinum could be safely substituted for cisplatin (65–67) or whether taxotere could be substituted for paclitaxel (68). However, there has been some controversy about the size of the benefit provided by paclitaxel (69). An investigator can reasonably ask, “What is the effect size of paclitaxel, and how much of this effect can I reasonably be certain is preserved by taxotere?”

Randomized Phase 3 Trials

There are several design features that may be considered for Phase 3 trials. Some are more pertinent than others to gynecologic oncology trials. The most important feature to be considered is treatment randomization. A study with this feature, a randomized clinical trial (RCT), has several scientific advantages. First, both the known and unknown prognostic factors tend to be distributed similarly across the treatment groups when a trial implements randomized treatments. Second, a potential source of differential selection bias is eliminated. This bias could

occur when there is an association between treatment choice and prognosis. It need not be intentional. When a physician's interest in a trial or a patient's decision to participate in the trial depends on the assigned treatment, a nonrandom association between treatment and prognosis can be introduced. Finally, randomization provides the theoretical underpinning for the significance test (70). In other words, the probability of a false-positive trial as stated in the study design is justified with randomization. It is important to recognize that these advantages, which are provided by randomizing the study treatments, are forfeited when all of the randomized patients are not included in the final analyses.

It is sometimes argued that since many factors that influence prognosis are known, perhaps other approaches to allocating treatments can be considered, and statistical models should be used to adjust for any imbalances in prognosis. However, the conclusions from this type of trial must be conditioned on the completeness of knowledge about the disease and the acceptability of the modeling assumptions. If the disease is moderately unpredictable with regard to the outcome, or the statistical model is inappropriate, then the conclusions are suspect. Results from nonrandomized studies can polarize the medical community. They frequently provide enough evidence for those who already support the conclusions but insufficient evidence for those who are skeptical.

Kunz and Oxman (71) have compared the results from overviews of randomized and nonrandomized clinical trials that evaluated the same intervention. They reported that the nonrandomized studies tended to overestimate the treatment effect from the randomized trials by 76% to 160%. Schulz et al. (72) compared 33 randomized controlled trials that had inadequate concealment of the random treatment assignments to studies that had adequate concealment. They found that studies with inadequate concealment tended to overestimate the treatment effect (relative odds) by 40%. Some investigators do not appreciate the importance of concealment and will go to considerable lengths to subvert it (73). When the randomization technique requires pregenerated random treatment assignments, one must guarantee that the investigators, who are enrolling patients, do not have access to the assignment lists.

The patient–physician relationship can occasionally be challenged by introducing the concept of treatment randomization (74). Patients may prefer a sense of confidence from their physician regarding the “best” therapy for them. However, physicians involved in a RCT must honestly acknowledge that the best therapy is unknown and that a RCT is preferred to continued ignorance. One survey of 600 women seen in a breast clinic suggests that 90% of women prefer their doctor to admit uncertainty about the best treatment option, rather than give them false hope (75).

Randomization techniques. The simplest approach to randomization is to assign treatments based on a coin flip, sequential digits from random number tables, or computerized pseudo-random number generators. On average, each patient has a defined probability of being allocated to a particular study treatment, when he or she enters the study. While this approach is simple, the statistical efficiency of the analyses can be enhanced by constraining the randomization so that each treatment is allocated an equal number of times. Permuted block randomization is sometimes used to promote equal treatment-group sizes. A block can be created by shuffling a fixed number of cards for each treatment and then assigning the patients according to the random order of the deck. After completing each block there are an equal number of patients assigned to the treatment groups. For example, consider a trial comparing treatments A and B. There are 6 possible ways the block can be ordered when the block size is 4: AABB, ABBA, BBAA, BABA, ABAB, and BAAB. A sufficient number of assignments for a RCT can be created by

randomly selecting a series of blocks from the 6 distinct possibilities. There are 3 features of blocked randomization that may be problematic. First, the probability of a particular treatment being allocated is not the same throughout the study, as in simple randomization. Taking the example above, every 4th treatment is predetermined by the previous 3 allocations. Second, the use of small blocks in a single-clinic study may undermine concealment and allow an investigator to deduce the next treatment. This potential problem can be corrected by continually changing the block size throughout the assignment list. Third, large block sizes can subvert the benefits of blocking. As block sizes increase, the procedure resembles simple randomization.

The statistical efficiency of the study can be further enhanced by stratifying patients into groups with similar prognoses and using separate lists of blocked treatments for each stratum. This procedure is called stratified block randomization. It is worth noting that using simple randomization within strata would defeat the purpose of stratification, since this is equivalent to using simple randomization for all patients. Likewise, trials that stratify on too many prognostic factors are likely to have many uncompleted treatment blocks at the end of the study, which also defeats the intent of blocking (76).

When it is desirable to balance on more than a few prognostic factors, an alternative is dynamic treatment allocation; one particular type being minimization. Whereas stratified block randomization will balance treatment assignments within each combination of the various factor levels, minimization tends to balance treatments within each level of the factor separately. Each time a new patient is entered into the study, the number of individuals who share any of the prognostic characteristics of the new patient is tabulated. A metric, which measures the imbalance of these factors among the study treatments, is computed as if the new patient were allocated to each of the study treatments in turn. The patient is then allocated to the treatment that would favor the greatest degree of balance. In the event that the procedure indicates equal preference for two or more possible treatment allocations, simple randomization can be used to determine the patient's treatment assignment.

Masking Treatments

Concealment Concealment refers to the procedure in which the assigned study treatment is not revealed to the patient or the investigator until after the subject has successfully enrolled in the study. The purpose of concealment is to eliminate a bias which can arise from an individual's decision to participate in the study depending on the treatment assignment (77). Concealment is an essential component of randomized clinical trials.

Blinding Blinding is a procedure that prevents the patient or physician from knowing which treatment is being used. In a single-blinded study the patient is unaware of which study treatment she is receiving. A double-blinded study results in a situation in which neither the patient nor the health care provider is aware of that information. One purpose of blinding is to avoid measurement bias, particularly differential measurement bias (see Endpoints section). This type of bias occurs when the value of a measurement is influenced by the knowledge of which treatment is being received (see Historical Perspective section). It can occur when the measurement of an endpoint is in part or totally subjective. Most methods for assessing pain are subjective and require treatment blinding in order to promote the study's validity.

Oncology trials frequently do not implement blinding for several reasons. It is rather difficult to blind treatments when various treatment modalities are used (e.g., surgery versus radiation therapy, or intravenous versus oral administrations), when good medical practice is jeopardized (e.g., special tests are required to monitor toxicity due to particular treatments),

or when it is logistically difficult (e.g., the evaluating physician must be kept isolated from the treatment of the patient). In the absence of blinding, care should be taken that the method of measuring the endpoint is precisely stated in the protocol and consistently applied to each patient uniformly. Trials that assess quality of life or relief from symptoms should give serious consideration to treatment blinding.

Schulz et al. (78) have reviewed 110 randomized clinical trials published between 1990 and 1991 from 4 journals dedicated to obstetrics and gynecology. Thirty-one of these trials reported being double-blinded. Schultz et al. conclude that blinding should have been used more often, despite frequent impediments. Moreover, blinding seemed to have been compromised in at least 3 of the trials where it was implemented.

Placebo A placebo is an inert treatment. Placebos blind the patient, and usually the physician as well, to the knowledge of whether an experimental or an inert treatment is being given. Placebos are frequently used in trials where there is no accepted standard treatment and the endpoint is susceptible to measurement bias. The use of a placebo is also important when the endpoint can be affected by the patient's psychological response to the knowledge of receiving therapy combined with a belief that the therapy is effective. This phenomenon is aptly named the "placebo effect." In such circumstances, the use of a placebo provides a treatment-to-control comparison that measures only the therapeutic effect. Note that the "placebo effect" is a distinctly different type of measurement bias from those that have been previously discussed. Careful ethical considerations must precede the use of a placebo or sham procedure in any clinical trial (79).

GOG Protocol 137 (A Randomized Double-Blinded Trial of Estrogen Replacement Therapy versus Placebo in Women with Stage I or II Endometrial Adenocarcinoma) was a randomized double-blinded comparison of estrogen replacement therapy versus a placebo in women who had a total abdominal hysterectomy and bilateral salpingo-oophorectomy for early-stage endometrial cancer. One primary reason for the use of a placebo in this trial was the potential for differential measurement bias being introduced by the physician monitoring patients on estrogens much more closely due to the anticipation of adverse events.

Factorial Designs

Factorial designs are used when several interventions are to be studied simultaneously. The term *factorial* arises from historical terminology in which the treatments were referred to as factors. Each factor has corresponding levels; for example, an investigator may wish to compare a study agent administered at 3 dose levels: high-dose, medium-dose, and none. The total number of factor combinations being studied is the product of the number of levels for each factor or treatment. For example, a trial that evaluates treatment A at three levels and treatment B at 2 levels is called a 3-by-2 (denoted 3×2) factorial design. If the relative effects due to the various levels of treatment A are independent of the levels of B, the two treatments (A and B) can be evaluated simultaneously. The factorial design provides a significant reduction in the required sample size when compared to a study that evaluates all levels of A and B separately. The key assumption necessary for a factorial design is that all treatments can be given simultaneously without interaction or interference.

The most commonly utilized factorial design is the 2×2 factorial design that includes 2 distinct treatment regimens at each of 2 factor levels. For example, suppose individuals entering a cancer prevention trial are randomly assigned to receive vitamin E and beta carotene while the respective factor levels are placebo-A or 50 mg/day for vitamin E, and placebo-B or 20 mg/day for beta carotene. There are 4 treatment

combinations. In a standard 2×2 design the main effect of vitamin E can be ascertained by utilizing information from each of the 4 treatment groups. In some studies, however, the main effects may be of secondary importance compared to the “interaction” between each factor. An interaction exists when the effect due to 1 of the factors (i.e., treatment A) depends on the level of the other factor (treatment B). In drug discovery, a “positive” interaction may imply a synergistic effect of 2 drugs in combination, that is, the effect of the combination therapy is greater than the sum of the individual additive effects. Reliable tests of an interaction require a relatively large number of patients in each of the 4 treatment groups. If potential treatment interaction cannot reasonably be ruled out or there is interest in possible interactions, then attention to the statistical power of such tests is an important part of designing and interpreting the study results (80).

Hypothesis Test

A hypothesis is a conjecture based on prior experiences that leads to refutable predictions (81). A hypothesis is frequently framed in the context of either a null or an alternative hypothesis. A null hypothesis may postulate that a treatment does not influence patients’ outcomes. The alternative hypothesis is that a particular, well-defined treatment approach will influence the patients’ outcomes to a prespecified degree. These hypotheses cast the purpose of the trial into a clear framework. During the study design the investigators select a test statistic from an appropriate statistical procedure (e.g., an F-statistic from an analysis of variance, or a chi-square statistic from a logistic model) that evaluates the degree to which the study data support the null hypothesis. A Type I error is committed when the null hypothesis is in fact true, but the test statistic leads the investigator to incorrectly conclude it is false. Committing the Type I error would be disastrous if it means discontinuing the use of an active control treatment that is well tolerated and substituting an experimental therapy that is more toxic but, in reality, not better. A Type II error is committed when the null hypothesis is not true, but the test statistic leads the investigator to erroneously conclude that it is true. Type II errors commonly occur in studies that involve too few subjects to reliably estimate clinically important treatment effects. Prospectively specifying the null hypothesis, the appropriate statistical method for the analysis, the test statistic and quantifying the acceptable probabilities of Type I error (i.e., α -level) and Type II error are essential elements for determining the appropriate design and sample size for a particular trial.

p-Value

At times statisticians play the role of the conservative physician, cautiously prescribing a significance test only when it is appropriate. There is a general concern that the p -value is overused, even abused, and overemphasized. A common misconception is that the p -value is the probability that the null hypothesis is true. The null hypothesis is either true or false, and so it is not subject to a probability statement. It is the inference that an investigator makes, based on his or her data, that is susceptible to error. The p -value is simply the probability that the test statistic would be as extreme or even more extreme, if the null hypothesis was in fact true (see hypothesis test section).

Misconceptions about the p -value may arise in part from a poor distinction between the p -value and the α -level of a study (82). The α -level is the probability of the test statistic rejecting the null hypothesis when it is true. It is specified during the design phase of the study, and is unaltered by the results obtained. The p -value results from a statistical test performed on the observed data.

Translational Research

Many modern clinical trials often involve the systematic collection and banking of biologic materials from the participants. The materials may include serum, plasma, urine, buccal cells, or tumor tissue, which are collected and stored in a bank. The biologic materials together with the clinical data can then be used to understand how a biologic effect translates into the treatment effect on the patient population. This translation gives rise to the concept of translational research (TR). In translational research, discoveries in laboratory science are translated into practical applications. The flow of information from TR studies is a 2 way street: 1) more complete understanding of tumor biology and 2) more effective treatments for patients.

The goal in this section is to provide clinical and laboratory scientists with some fundamental information needed to design, implement, and analyze the data from TR studies. The following sections develop the concepts for: (a) biomarker discovery and verification, and (b) biomarker validation. In short, these steps are presented in Figure 17.3 (Discovery and Test Validation Stage). We provide insights into what goals and expectations a researcher can have when performing a biomarker study. With this knowledge, the reader can avoid some of the errors and biases that have plagued translational research and led to false, misreported, or misleading reports.

Biospecimen Collection

A widely used definition of a biomarker is “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to an intervention” (83). Biomarkers can be measurements of macromolecules (DNA, RNA, proteins, lipids), cells, or processes that describe a normal or abnormal biologic state in a patient. From the paradigm of translational research described above, biomarkers can inform investigators about a patient’s diagnosis, prognosis, prediction of response to therapy (i.e., effect modifier), or prediction of a clinical outcome (i.e., surrogate endpoint).

Generally speaking, biomarkers can be diagnostic or prognostic. A diagnostic biomarker is designed to identify the presence of a disease or other condition, while a prognostic biomarker is an indicator that helps researchers in predicting the course of a patient’s disease. Prognostic biomarkers are used to estimate the risk of a future clinical outcomes, and examples include stage of the disease, histology of the tumor, or patient’s performance status. A biomarker may also be deemed predictive, and as such, it can be used to modify the estimated risk of a future outcome, but only when a particular type of treatment is taken. In breast cancer patients, examples of predictive biomarkers are estrogen receptor status when the treatment is tamoxifen or *Her2/neu* status when the treatment is trastuzumab. The phrase “treatment selection marker” has become the preferred terminology for a predictive biomarker to avoid confusion with other uses of the word “predictive”. For our immediate purposes here we will view predictive markers as a special class of prognostic markers and primarily focus on prognostic biomarker studies. Only in the section describing studies involving targeted therapies will the distinction be made.

The biologic specimens used in a study are typically gathered either prospectively or retrospectively. In the prospective approach, patients are identified and then followed forward in time. There are several advantages to the prospective approach. First, patient enrollment can focus on enrolling only individuals from the intended target population. Second, the procedures for collecting and preparing specimens can be tailored to the intended laboratory procedures. Third, the quality

Biomarker Development for High-throughput Technologies**Classifier Development Phase**

- **Probe Discovery:** Identify a subset of genes/proteins associated with the clinical outcome of interest.
- **Probe Verification:** Confirm measurements on selected genes/proteins using alternate laboratory techniques, like IHC or Rt-PCR.
- **Classifier Development:** Use the confirmed genes/proteins to develop a model (classifier) that appears to predict clinical outcome.

Classifier Verification Phase

- **Model Verification:** Confirm the model's properties using a small independent sample of individuals or cross-classification techniques.
- **Document Classifier:** Document the computational procedures and criteria for interpreting the lock-down model.

Classifier Validation

- **Validation:** Evaluate the model's predictive accuracy in a sample of individuals representative of the target population. Any changes to the procedures or the lock-down model to improve the classifier will require further validation.

For additional information see National Research Council. *Evolution of Translational Omics: Lessons Learned and the Path Forward*. Washington, DC: The National Academies Press, 2012 (147).

FIGURE 17.3. Biomarker development for high-throughput technologies.

control procedures for collecting the clinical data can target those data items that are required for the specific study objectives. Fourth, the patient's treatment and follow-up assessments can be standardized and optimized in accordance with the goals of the study. When samples are retrospectively collected, the laboratory analysis is performed using previously archived specimens that may have been originally collected for another purpose. The investigator using a retrospective approach is a prisoner to the procedures that were set down before the current study goals were contemplated and therefore, they may not be optimal for his intended objectives. For instance, the samples may have come from patients who are not representative of the target population. This reduces the generalizability of the study results. The specimens may have been obtained, prepared or stored using outdated or less than optimal procedures for his laboratory tests. This could introduce biases in the measurements or reduce the power of the study.

Biomarker Development Process

In the following sections, we discuss a common TR study design for a biomarker: (a) biomarker discovery and (b) biomarker validation. In short, these steps are presented in Figure 17.3 (Discovery and Test Validation Stage).

Discovery Phase

Regardless of whether the samples were retrospectively or prospectively collected, many studies are designed to discover biomarkers with clinical utility, from among many potentially useful biomarkers.

Since the invention of microarray technology and related high-throughput technologies, researchers have been able to compile large amounts of information and an enormous pool of potential biomarkers. These so called high-throughput platforms have become commonly used experimental platforms in the biologic realm (84). A high-throughput platform is designed to measure large numbers (thousands or millions) of signatures in a biologic organism at a given time point. These platforms are a function of the postgenomic era and are often used to determine how genomic expression is regulated or involved in

biologic processes. The technologies in Table 17.1 use hybridization and sequence-based platforms such as gene expression microarrays and RNA-Seq to obtain data matrices.

Several of the common high-throughput assay platforms used in experiments designed for cancer diagnosis are listed in Table 17.1. These platforms were chosen to illustrate the diversity of platforms available for interrogating deoxyribonucleic acid (DNA), ribonucleic acid (RNA), or proteins.

Preprocessing High-Throughput (HT) Platforms

In short, pre-processing algorithms are required in nearly all high-throughput technologies listed in Table 17.1. This is due to the fact that HT platforms measure both biologic signal and technical signal. Therefore, the goal of preprocessing algorithms is removal of the technical signal. This technical signal can be considered in terms of background correction and normalization to adjust across experiments. The background corrections and normalization account for technical artifacts that can occur due to either the array construction or laboratory procedures that introduce systematic errors in the signal on individual arrays or across arrays. Often these pre-processing techniques are specific to the platform employed (see, for example, Miecznikowski et al. [85]) and therefore it is impractical to review all of the available pre-processing methods here.

Type I Error and Multiple Testing

The experiments performed in the HT discovery phase often have a goal of simply narrowing down the genome or proteome to a subset of potentially relevant biomarkers. In this sense, the scientists are performing a data reduction where the goal is to choose a subset of markers from the high-throughput scope that are related or associated with clinical outcome. The association with the outcome is assessed using a null hypothesis for each biomarker and summarizing “significance” with a p -value. In this case, the interpretation of each p -value differs slightly from a study with a single null hypothesis (See Hypothesis Test and p -value sections).

When the Type I error is limited to 5% for a single hypothesis, then there is only a 1-in-20 chance of rejecting that null hypothesis, if it is in fact true. This is a relatively uncommon

Table 17.1 A Summary of Discovery Platforms, The Material Analyzed in the Platform and Recent Cancer Biomarker Discovery Studies Using the Given Platform

Platforms	Material	Cancer Studies
aCGH microarray	DNA	(86,88–95)
Gene expression microarray	mRNA	(96–105)
RNA—Seq	Transcriptomics	(106,107)
DNA methylation	DNA	(108)
Mass spectrometry	Peptide/proteomics	(109–114)

occurrence. When there are 10,000 null hypotheses tested, as may be typical for some HT studies, even if all of the null hypotheses were true, one would expect 500 null hypotheses to be rejected at the 5% significance level. The chance of committing a Type I error over the entire study should no longer be considered an uncommon occurrence.

Therefore, during the discovery phase of a HT experiment the goal is to limit the Type I error rate. That is, HT studies are designed to limit the number of false positives, denoted by V in Table 17.2A. Table 17.2B lists some alternative approaches to controlling the Type I error rate during the discovery phase of the experiment. Statistically significant or interesting markers are determined from hypothesis testing in light of controlling one of the Type I error rates listed in Table 17.2B.

Confirmation and Verification

In order to have reasonable power in light of multiple testing, the Type I errors in Table 17.2A tend to be more liberal (more likely to reject null hypotheses) than standard scientific significance testing procedures. Thus, any markers from the discovery phase should be confirmed or verified using other methods, such as immunohistochemical (IHC) assays or reverse transcription polymerase chain reaction (RT-PCR). These verification platforms could use either the same samples from the discovery phase or a new independent set of samples. The goal for this step is to confirm that the biomarker signal from the discovery platform is accurately measuring the expression of the desired gene, protein or RNA.

Including a confirmation step ensures researchers that their discovery markers can be confirmed using other platforms. This provides some reassurance in the ability of the markers to be confirmed on independent samples from possibly different institutions with, possibly, differing methods of assessment. Methods that describe how to correlate RT-PCR and IHC signals with their microarray counterparts can be found in Press et al. (115), van den Broek and van de Vijver (116), McShane et al. (117), Esteban et al. (118).

Table 17.2A A summary of results from analyzing multiple hypothesis tests.

	H_0 Retained	H_0 Rejected	Total
H_0 True	U	V	M_0
H_0 False	T	Q	M_1
	M—R	R	M

M_0 and M_1 are considered as fixed (unknown) parameters representing the number of true nulls and the number of true alternatives, respectively. The random variables U and Q represent the number of the correct decisions, while the random variables T and V represent the number of incorrect decisions. V is the number of false positives.

In certain immunohistochemistry assays the results should be performed by at least 2 different observers who are blinded to the clinical data. This may alleviate the subjectivity in these experiments since IHC assays require selection of best regions to score and subjective measurements of staining intensity and percentage of stained cells.

Validation Phase

Various statistical models can be fit using the data in the discovery phase. At the end of the discovery phase there should be a complete specification of the marker assay method and model, and thorough documentation of the (final) lock-down model. The fully specified precise lock-down model will be evaluated using a validation dataset. Note, for example, this must include specifying all coefficients in the classification model and any of the rules for deciding the level of a biomarker.

Validation in biomarker experiments should always involve an independent dataset, that is, data from patients that were not included in any of the discovery dataset(s). Note that internal validation procedures such as cross-validation, boot strapping, or other data resampling methods are useful to give insights into issues such as bias and variance of regression parameter estimates and stability of the model derived. In these internal validation procedures, some portion of the data is held out (test set), while a model is built on the remaining portion (training set). A limitation of these internal procedures is that there may be biases that affect the training and test sets equally. For example, if the set of specimens for confirmation are collected in the same laboratory, processed by the same technician, and run on the same equipment, then peculiarities of that data (equipment, lab, technician) will be shared between the samples used to develop the computational model and the samples used to evaluate the model.

Table 17.2B Summary of Type I Errors

Abbreviation	Name	Quantity
FWER	Family Wise Error Rate	$\Pr(V > 1)$
k-FWER	Generalized Family Wise Error Rate	$\Pr(V > k)$
FDR	False Discovery Rate	$E[V/R]$
k-FDR	Generalized False Discovery Rate	
PCER	Per comparison error rate	$E[V]/M$
TPPPF	Tail probabilities for the proportion of false positives	$\Pr(V/R) > q$

Summaries of Type I errors using random variables defined in Table 2a. See similar tables in Nichols and Hayasaka [2003] (Nichols and Hayasaka 2003) and Table 15.1 in Gentleman et al. [2005] (Gentleman, Carey et al. 2005). Note that $I(\cdot)$ in the equation for k-FDR denotes the indicator function and $\max(\cdot)$ denotes the maximum operator. Further note that q in TPPPF should be determined prior to testing. $\Pr(\cdot)$ denotes probability, and $E[\cdot]$ denotes expectation.

Even with the requirement of an independent dataset, there may still be levels of validation evidence. For example, a lower level of validation evidence may be independent sets of specimens and clinical data collected at a single institution using carefully controlled protocols, with samples from the same patient population. Meanwhile, a higher level of validation evidence would be independent sets of specimens and clinical data collected at multiple institutions.

Additionally, it should be stressed that the independent validation dataset must be relevant to the intended use of the candidate biomarker test. Patients in the independent dataset should have the same type of disease, the same stage and same clinical setting for which the candidate test is intended to be used in the future. Ideally, the specimens for independent confirmation will have been collected at a different point in time, at different institutions, from a different patient population, with samples processed in a different laboratory to demonstrate that the test has broad applicability and is not overfit to any particular situation.

Publicly Available Data

These datasets can help with the development process, and further they can complete the puzzle in systems biology, for example, provide the proteomics story if you only have genomic data. They can be used in an integrative analysis and a meta-analysis. These meta-analyses can strengthen the conclusions drawn from an individual researcher's study. They may also offer insights from other study populations.

As deoxyribonucleic acid (DNA) microarray technology has been widely applied to detect gene activity changes in many areas of biomedical research, development and curation of online microarray data repositories are at the forefront of research endeavors to use and reuse this mounting deluge of data. Several representative repositories of microarray datasets are ArrayExpress at the webpage <http://www.ebi.ac.uk/arrayexpress/>, Gene Expression Omnibus (GEO) (119) at the webpage <http://www.ncbi.nlm.nih.gov/geo/>, Stanford Microarray Database (SMD) at the webpage <http://smd.stanford.edu/> and Center for Information Biology Gene Expression Database (CIBEX) (120) at the webpage <http://cibex.nig.ac.jp/index.jsp>. Also a new database called Anduril which has been recently developed and described in Ovaska et al. (121) now provides comprehensive storage of the massive data including single base pair mutation, copy number change or deletions of genes, differential gene expression, and epigenetic changes like methylation profiles. A somewhat recent comparison of the available microarray databases was provided in Gardiner-Garden and Littlejohn (122). Statistical packages in R have also been created that allows users to easily import data from databases like ArrayExpress into Bioconductor packages (123).

Concordant with the development of online data repositories, researchers have developed specific data standards required for microarray analysis. The data standard concept describes the minimum information about a microarray experiment (MIAME) that is needed to enable the interpretation of the results of the experiment and to potentially reproduce the experiment (124). MIAME compliance will ensure that biological properties of the samples and the phenotypes that were assayed were correctly recorded, thus, ensuring, that the data can be quickly assessed for its suitability in studying new questions. The public repositories including ArrayExpress (146), GEO (125), and CIBEX (120) are all designed to hold MIAME compliant microarray data.

Especially exciting for oncologists, multiple platforms of microarray data from The Cancer Genome Atlas (TCGA) are now available through the data portal at <http://tcga-data.nci.nih.gov/tcga/tcgaHome2.jsp>. The TCGA project is further described in Stratton et al. (126), but in short, represents one of the first large-scale attempts to study the multiple types of genetic mutations involved in multiple cancer types from

different cohorts of patients. Initially, the pilot projects studied glioblastoma multiforma (GBM) and cystadenocarcinoma of the ovary, but have now expanded to cover roughly 20 different cancer types. For each cancer type, the patient cohorts (collected from different sites) include several hundred individuals and the platform techniques include gene expression profiling, copy number variation profiling, SNP genotyping, methylation profiling, and microRNA profiling. These data will be made publicly available, making the TCGA dataset a great resource for future research using meta-analysis and integrative analysis techniques that were not previously available.

Developing Translational Research Studies and Reporting Results

Guidelines have been developed to promote accurate and complete reporting of results from biomarker studies. Throughout this section, the importance of having well-defined questions for the proposed data is stressed. In other words, serious thought, planning, and discussions amongst a team of scientists are necessary to successfully perform biomarker analysis, including discovery, verification, and validation.

In the discovery phase it is important that the proposed technology has been validated, see for example, technical replication studies in Strand et al. (127), Callesen et al. (128); Leyland-Jones et al. (129), De Cecco et al. (130), Hicks et al. (131), Benton et al. (132), Freidin et al. (133), and Lawrie et al. (134). During the discovery phase, it is also important to consider differences in material preparation, for example, frozen tissue samples versus paraffin embedded tissues as discussed in Nowak et al. (135), and Mittempergher et al. (136). During the verification phase, these issues also may play a role; however, other concerns may arise such as the level of concordance in signal necessary between the discovery platform and the verification platform. Ultimately, after discovery and verification, a lockdown model is carried forth to validation. This, so called, lockdown model can be interpreted in a decision theoretic setting; each future sample must be classified or the outcome predicted based only on the model and a given sample signal from the intended technology.

In the validation phase, it is important to note that there is a major difference between answering *a priori* defined hypotheses and providing conclusions from exploratory analyses. Conclusions drawn from exploratory data analysis are descriptive results and typically need to be confirmed in a validation dataset, while *a priori* hypothesis lead to stronger conclusions and do not necessarily need an external validation. Care should be given in reporting unanticipated significant effects, as these are most likely due to chance and thus unlikely to be validated in other studies. Most importantly, researchers should keep in mind that, in the long term, the success of biomarker studies should be measured by the clinical improvement in patient outcomes.

There have been a prodigious number of biomarker studies reported in the literature; however, a surprising number of these results are irreproducible. The reasons for these discrepancies may lie in the differences in methodological procedures, inadequate control of false-positive findings, improper validation procedures, variability in the patient sampling, or any number of other differences in study design, conduct, or analytical procedures. Many published studies lack adequate information that would allow an evaluation of quality or comparability. In order to promote clear and complete reporting of biomarker studies, the REMARK guidelines have been developed (137). These guidelines make specific recommendations for preparing translational research presentations, reports, and publications with regard to describing patient and sample characteristics, assay methodology, study design, methods of data analysis, and results. While these recommendations have been distilled into bullets in Table 17.3, useful additional information can be found in the REMARK document (137).

Table 17.3 **REMARK Criteria: Reporting Recommendations for Tumor MARKer Prognostic Studies**

Reporting Recommendations for Tumor Marker Prognostic Studies (REMARK)

Introduction

1. State the marker examined, the study objectives, and any prespecified hypotheses.

Materials and methods

Patients

2. Describe the characteristics (e.g., disease stage or comorbidities) of the study patients, including their source and inclusion and exclusion criteria.
3. Describe treatments received and how chosen (e.g., randomized or rule-based).

Specimen characteristics

4. Describe type of biologic material used (including control samples) and methods of preservation and storage.

Assay methods

5. Specify the assay method used and provide (or reference) a detailed protocol, including specific reagents or kits used, quality control procedures, reproducibility assessments, quantitation methods, and scoring and reporting protocols. Specify whether and how assays were performed blinded to the study endpoint.

Study design

6. State the method of case selection, including whether prospective or retrospective and whether stratification or matching (e.g., by stage of disease or age) was used. Specify the time period from which cases were taken, the end of the follow-up period, and the median follow-up time.
7. Precisely define all clinical endpoints examined.
8. List all candidate variables initially examined.
9. Give rationale for sample size; if the study was designed to detect a specific effect size, give the target power and effect size.

Statistical analysis methods

10. Specify all statistical methods, including details of any variable selection procedures and other model-building issues, how model assumptions were verified, and how missing data were handled.
11. Clarify how marker values were handled in the analyses; if relevant, describe methods used for cutpoint determination.

Results

Data

12. Describe the flow of patients through the study, including the number of patients participating in each stage of the analysis (a diagram may be helpful), and reasons for dropout. Specifically, both overall and for each subgroup extensively examined report the number of patients and the number of events.
13. Report distribution of basic demographic characteristics (at least age and sex), standard (disease-specific) prognostic variables, and tumor marker, including numbers of missing values.

Analysis and presentation

14. Show the relation of the marker to standard prognostic variables.
15. Present univariate analyses showing the relation between the marker and outcome, with the estimated effect (e.g., hazard ratio and survival probability). Preferably provide similar analyses for all other variables being analyzed. For the effect of a tumor marker on a time-to-event outcome, a Kaplan-Meier plot is recommended.
16. For key multivariate analyses, report estimated effects (e.g., hazard ratio) with confidence intervals for the marker and, at least for the final model, all other variables in the model.
17. Among reported results, provide estimated effects with confidence intervals from an analysis in which the marker and standard prognostic variables are included, regardless of their statistical significance.
18. If done, report results of further investigations, such as checking assumptions, sensitivity analyses, and internal validation.

Discussion

19. Interpret the results in the context of the prespecified hypotheses and other relevant studies, and include a discussion of limitations of the study.
20. Discuss implications for future research and clinical value.

Gene expression profiles from formalin fixed paraffin embedded breast cancer tissue are largely comparable to fresh frozen matched tissue. *PLoS One*. 2011;6(2):e17163.

Clinical Trials Involving Targeted Therapies

As previously mentioned, biomarkers can be used to diagnose a disease, to assess prognosis, to select appropriate treatments (predictive), or to assess treatment outcome (surrogate endpoint). Thus, biomarkers can be incorporated into many aspects of clinical practice and research once validated. There are 2 types of biomarker validation to consider: analytic and clinical validation. Analytic validation refers to obtaining evidence that the biomarker assay result is reproducible under a variety of conditions and that the assay is shown to accurately measure the intended analyte. Some aspects of analytic validation are presented in the Translational Research section. Analytic validation of the biomarker assay is essential before a biomarker can be clinically validated. Clinical validation involves demonstrating that the biomarker is “fit for purpose.” That is, it functions properly for its intended use as a diagnostic, prognostic, treatment selective, or surrogate marker. The rigor needed to evaluate the clinical utility of a biomarker has recently been emphasized in light of several failed attempts at validating complex biomarkers (138–140). This section will focus on trial design considerations for evaluating the clinical utility of a predictive biomarker. The term *predictive* biomarker has been used to differentiate a biomarker’s properties, over and above that of being prognostic. A predictive biomarker is prognostic when a particular treatment (or class of treatments) is prescribed. For example, *Her2/neu* is considered a predictive biomarker for Herceptin in the treatment of women diagnosed with breast cancer. There has been a movement toward using the term “treatment selection biomarker” in the literature instead.

A clinically useful treatment selection biomarker will identify patients with diseases that are either resistant or sensitive to a specific targeted therapy. These markers can be used to improve the efficiency of a study. Suppose the probability of response to standard treatment is 20% in the general patient population. Furthermore, suppose that 20% of the individuals in the general patient population are very responsive to a new targeted treatment, such that, when the targeted agent is added to the standard treatment, the probability of response is 60% among this sensitive subgroup, but unchanged in the nonsensitive subgroup. If the new treatment is combined with the standard treatment in the general population, regardless of their sensitivity status, then the expected probability of response would only be 28% (ie., 20% of the population have 60% response rate, and 80% have 20% response rate = $0.20 \times 0.60 + 0.80 \times 0.20 = 0.28$). If a randomized trial was now designed to compare standard treatment versus standard treatment with the new agent, then over 1000 patients would need to be enrolled in order to reliably detect this size of a treatment effect (Table 17.4). On the other hand, if the study used a perfectly accurate biomarker (sensitivity = 100% and specificity = 100%) to restrict enrollment to treatment-sensitive patients, then only 60 patients would be needed for the study (Table 17.4) and the expected number of patients needed to be screened would be about 300. However, biomarkers are seldom perfect. If a biomarker has only 80% sensitivity and 80% specificity, it could still be used to increase the prevalence of treatment-sensitive patients from 20% in the general population to 50% (also called the positive predictive value [PPV]) in the biomarker-enriched study population (Fig. 17.4). In this case the probability of response to the standard regimen with the new targeted agent in the enriched study population would be 40% ($0.50 \times 0.60 + 0.50 \times 0.20 = 0.40$). The two-arm trial designed with this imperfect biomarker to select sensitive patients would require 220 enrolled patients to reliably detect the difference in response rates (Table 17.4), and the expected number of patients needed to be screened would be about 688.

Table 17.4 Required Sample Size for a Randomized Trial with a Target Prevalence = 20%

Patient Population	Probability of Response		Sample Size
	Standard Therapy	Standard + Targeted Therapy	
Ideal Target Population ^a	0.20	0.60	60
General Population	0.20	0.28	1022
Enriched Population ^b	0.20	0.40	220

Design parameters: $H_0: P_0 \geq P_1$, $\alpha = 0.05$, $\beta = 0.10$.

^aSensitivity = 100%; specificity = 100%; number needed to screen = 300.

^bSensitivity = 80%; specificity = 80%; number needed to screen = 688.

In any study design where a biomarker is used to enrich the study sample with individuals considered most likely to respond, it may not be possible to differentiate between a failed treatment and a failed biomarker. Misspecification of the treatment target and misclassification of the tumor state are fundamental reasons for study failure. There can be a mismatch between the agent and the patient selection process in an enrichment design due to inadequate understanding of the true molecular target of the agent under study or use of an invalid surrogate endpoint biomarker (Fig. 17.5). A successful study depends on the degree to which the biomarker accurately measures the true state of the treatment’s target(s). Ideally, measuring the agent’s effect through the biomarker should measure the agent’s effect through the targeted pathway (highlighted in Fig. 17.5). If the treatment can influence the disease through pathways that are not captured by the biomarker, then the activity of the agent will be underestimated and potentially missed. For example, ovarian cancer mutations in the *BRCA1* and *BRCA2* genes identify tumors likely to respond to a class of agents referred to as Poly-ADP ribose polymerase inhibitors (PARPi). However, responses to PARPi have been observed among patients with no *BRCA* mutations (141). This suggests that markers of other biologic pathways will be needed to identify PARPi-sensitive tumors, such as markers for methylation of the *BRCA* genes or other types of dysfunction in the homologous recombination mechanism. Therefore, if the biomarkers that are used to define PARPi sensitivity included only *BRCA* mutation status, then sensitivity is sacrificed. On the other hand, if the markers for determining PARPi sensitivity include inconsequential mutations in the *BRCA* genes, then specificity is diminished. In enrichment studies, loss in sensitivity and specificity decreases the predictive value of the marker, which in turn decreases the chances that a study will identify active targeted agents (Table 17.4 and Fig. 17.4).

There are several alternative randomized trial designs for targeted therapies (142). One approach randomizes all patients from the target population and prospectively stratifies the random treatment assignment based on discrete values of the biomarker value. This design assesses a treatment effect in each of the discrete biomarker levels. Other designs randomize between treatment strategies, such as, assay-directed treatment versus standard therapy. These designs can be very inefficient and are generally not recommended (143). Study designs that adaptively modify the patient population when a planned interim analysis indicates that the biomarker identifies a subgroup of patients who are unlikely to respond or that utilize surrogate endpoints a lead-in randomized Phase II (seamless

FIGURE 17.4. Hypothetical biomarker-based enrichment study.

Phase II/III) study have also been proposed (144, 145). Currently, adaptive designs for targeted therapies are an area of intense biostatistical research.

Careful planning is necessary for incorporating biomarkers into clinical trials. The appropriate choice of the trial design

that incorporates a biomarker into a clinical trial depends on 1) the study objectives, 2) how well the agent's mechanism of action is understood, 3) how well the role of the target is understood, and 4) how well the selected biomarker captures the state of the target.

FIGURE 17.5. Schematic of the causal relationships and correlations between treatment, biomarker, biologic target, and clinical outcome.

CONCLUSION

The complexity of clinical trial design, conduct, analysis, and reporting has increased considerably over the past 60 years

since randomized treatment trials and public screening trials first began. It is difficult for a single clinician to consider initiating a clinical study since a study often requires extensive collaboration with other physicians, as well as with professionals from other disciplines such as biology, statistics, ethics, psychology, and economics.

18 Comparative Effectiveness Research in Gynecologic Oncology

LAURA J. HAVRILESKY ■ SHALINI L. KULASINGAM ■
ELIZABETH L. JEWELL ■ DAVID E. COHN

OVERVIEW OF COMPARATIVE EFFECTIVENESS RESEARCH

Introduction

Comparative effectiveness research (CER) is defined by the Institute of Medicine (IOM) as “the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition, or to improve the delivery of care.” With this definition, the IOM provides a framework for CER to exist, for example, in the development of a model to better understand the potential impact of an intervention (generation of evidence), or in the form of the comparison of 2 existing treatments of a condition (synthesis of evidence). As such, CER can take on various forms in differing clinical conditions.

The purpose of CER is “to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels” (1). In an effort to develop meaningful results from CER studies, the IOM recognized that “the most important priority of all should be the building of a broad and supportive infrastructure to carry out a sustainable CER strategy.” Furthermore, the IOM was mandated by the Obama administration to both define and establish priorities for CER. According to the IOM’s definition, CER is a way to identify what works for which patients and under what circumstances. Congress, in the American Recovery and Reinvestment Act (ARRA) of 2009, appropriated \$1.1 billion to jump-start the nation’s efforts to accelerate CER. Furthermore, ARRA created the Patient-Centered Outcomes Research Institute (PCORI), a public-private organization charged with setting national priorities for CER. In ARRA, IOM was also asked to recommend national priorities for research questions to be addressed by CER and supported by ARRA funds. The IOM provided its “100 Initial Priority Topics for Comparative Effectiveness Research,” which were then included in ARRA for priority funding (1). Many of these priorities are pertinent to gynecologic cancer research and are listed in Table 18.1. Although not comprehensive, this list provides insight into potential opportunities to utilize techniques and resources to study CER in gynecologic cancer. Despite the emphasis and funding to support CER, this field is not widely utilized in gynecologic cancer research, mainly due to the need for special

understanding of the tools for performing and analyzing CER and a relative lack of understanding of the application of CER in gynecologic cancer practice. Nonetheless, the field of CER has been gaining momentum within the gynecologic cancer community and has resulted in impactful information that continues to move the field forward.

History of CER

The concept of comparing interventions based on best available data is not new. Over the last 50 years, the ability to deliver health care of high quality and value has continued to be a conceptual priority that has been variably named. In the 1970s, new health care technologies were evaluated through the U.S. Congress Office of Technology Assessment. In the 1980s and 1990s, the terms “Effectiveness Research” and “Outcomes Research” were commonly utilized when evaluating the quality of health care interventions, and were often associated with the Agency for Health Care Policy and Research (which eventually became more formally organized as the Agency for Healthcare Research and Quality [AHRQ], now charged with improving “the quality, safety, efficiency, and effectiveness of health care for all Americans”). Despite the changes in names and focus, the ultimate goal of these groups and initiatives was to provide data to support the rational development and utilization of health care interventions. The formal process of developing a CER focus was initiated in the 2003 Medicare Modernization Act, which appropriated \$50 million to conduct research to address the needs and priorities related to improve outcomes, clinical effectiveness, and appropriateness of certain services and treatments. Data from these earlier efforts began to become integrated into coverage for these interventions in 2006, when the Centers for Medicare and Medicaid Services (CMS) provided support to the concept of inclusion of evidence-based decision-making and research into coverage determination policies. As the field has moved forward and become integrated into health care policy and coverage decisions, there has concurrently been an increasing concern that the field of CER will lead to rationing and denial of certain health care interventions. As the percentage of gross domestic policy spent on health care continues to rise beyond what is considered sustainable for the future, it is anticipated that CER will have a greater impact in establishing cost-effective and high-quality care.

Table 18.1 Priority Topics for Comparative Effectiveness Research Pertinent to Gynecologic Cancer Research

1. Compare the effectiveness of imaging technologies in diagnosing, staging, and monitoring patients with cancer, including positron emission tomography (PET), magnetic resonance imaging (MRI), and computed tomography (CT).
2. Compare the effectiveness of genetic and biomarker testing and usual care in preventing and treating ovarian cancer.
3. Compare the effectiveness of interventions (e.g., community-based multilevel interventions, simple health education, and usual care) to reduce health disparities in cancer.
4. Compare the effectiveness of different benefit design, utilization management, and cost-sharing strategies in improving health care access and quality in patients with cancer.
5. Compare the effectiveness of robotic assistance surgery and conventional surgery.
6. Compare the effectiveness of surgical resection, observation, or ablative techniques on disease-free and overall survival, tumor recurrence, quality of life, and toxicity in patients with liver metastases.
7. Compare the effectiveness of hospital-based palliative care and usual care on patient-reported outcomes and cost.

CER Methodology: “Real World” versus Randomized Controlled Trials

In practical terms, CER aims to compare 2 or more treatment strategies, either in clinical care or through modeling. This process of comparing strategies has historically been different from that of a conventional randomized controlled clinical trial (RCT), in which the subjects are carefully selected and many excluded from participation due to intercurrent illness or prior history. In CER, data is derived from “real world” subjects, settings, and treatments and is thus more apt to be generalizable to the overall population with a specific condition. Furthermore, RCTs tend to be of short duration and are underpowered to detect unexpected adverse effects or heterogeneity of treatment effects. Importantly, RCTs can be prohibitively expensive to complete and sometimes are not feasible to perform. While RCTs may be the best means by which one can assess whether an intervention works, it is an ineffective means to assess who will benefit from the intervention (2). CER methodologies often employ large clinical databases that are not restricted in their sample size, take into account those who do not participate in a research study, and are associated with a longer follow-up compared with RCTs. Given that these databases often have information regarding disease severity and subject comorbidity, a more complex analysis of the heterogeneity of treatment effects is feasible with database studies. Given the limitations of RCTs in the generalizability of an intervention and the strengths of CER in addressing this issue, there has been increasing interest in “pragmatic clinical trials,” which aim to combine the strengths of a RCT but are performed as larger population trials. These trials incorporate “real world” treatments, often include multiple outcomes, and are able to evaluate subgroup differences (3). It is anticipated that these trials will become increasingly important as the field of CER progresses.

CER and Cost-Effectiveness

While CER is broadly defined as any methodology that compares the benefits and harms of alternative strategies in health care, the most common CER studies fall within the field of

health economics. Health economic studies address the optimal allocation of economic resources in health care. The most common type of health economic evaluation is a cost-effectiveness analysis (CEA), a tool for comparing the relative values of 2 or more medical interventions. Therefore, a CEA fits under the umbrella of CER through its ability to inform decision-making regarding the financial implications of health care.

Summary

Comparative effectiveness research is becoming increasingly utilized by patients, providers, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels. With increasing pressure to control the costs and improve the quality of health care, CER will be an important means by which different treatments can be critically evaluated. While in its relative infancy, CER in gynecologic cancer is a field ready for development.

PRINCIPLES OF HEALTH ECONOMIC ANALYSES

This section will introduce basic types of health economic studies. The term “cost-effectiveness analysis” is commonly used as a catch-all term for any health economic analysis. In fact, there are several distinct forms of health economic evaluation, including CEA, cost-utility analysis (CUA), cost-minimization analysis (CMA), and cost-benefit analysis (CBA). CEA and CUA are the most frequently used health economic analyses. CEAs compare alternative interventions using a cost per unit of effectiveness such as a year of life gained (4). CUAs examine cost, effectiveness, and preferences for health outcomes. CMAs compare only cost. CBAs are less commonly used in health care and compare the total expected cost of each option against the total expected monetary benefit (4).

Cost-Effectiveness Analyses

CEA is defined by the United Kingdom’s National Institute for Health and Clinical Excellence (NICE) as an economic study design in which the consequences of different interventions are measured using a single outcome (e.g., years of life gained, deaths avoided) (5). A CEA is used to help prioritize the allocation of resources and to decide between one or more treatments or interventions. It compares a standard of care strategy to its more costly alternatives in terms of the additional cost per unit of effectiveness. Units of effectiveness in oncology CEA are most commonly expressed as additional survival time, but may be expressed in other terms such as the number of adverse events or additional procedures avoided or the number of cases of cancer prevented. This type of study is commonly used when a decision or health policy maker is operating within a given budget and is considering a limited range of options (4). When an intervention costs more and is also more effective than its alternative, the cost-effectiveness comparison is expressed as an incremental cost-effectiveness ratio (ICER) or the ratio of the difference in costs to the difference in effectiveness between 2 strategies.

Cost-Minimization Analyses

In some cases, alternative medical decisions have approximately equivalent effectiveness but potentially different costs. In such cases, the effectiveness component of a CEA may not be needed. CMAs assume comparable effectiveness between strategies and

choose a preferred strategy based on the mean cost of each (6). For example, a recent decision analysis comparing the costs of three different surgical approaches to endometrial cancer staging assumed equal survival outcomes between strategies and therefore did not incorporate effectiveness (7).

Cost-Utility Analyses

CUA is a form of CEA in which effectiveness is adjusted based on the quality of life that is associated with each strategy. In CUAs, *utilities* are the measurement used for quality of life and represent the preferences of an individual or a society for a particular health outcome. A utility is a number between 0 and 1, with 1 representing perfect health and 0 representing death. The most common metric used for comparison of strategies in a CUA is a quality-adjusted life year (QALY). The QALY quantifies both differences in survival and in quality of life between strategies. In an oncology CUA, the QALY is usually derived as the product of the length of survival in a specific health state and the utility representing the quality of life in that state. For example, 1 year of additional survival in a health state of utility 0.8 is equivalent to 0.8 QALYs. CUAs are preferred when both morbidity and mortality are affected by the proposed medical intervention or when quality of life related to the intervention being examined is a major concern. QALYs are the recommended outcome for health economic analyses if utility scores are available (8).

Cost-Benefit Analyses

CBA is a more global type of economic analysis than CEA and CUA in that it can be used to evaluate programs outside the realm of health care, such as general public policy decisions. A CBA measures both the costs and the consequences of each intervention in monetary units. The outcome of a CBA can be expressed as a ratio of benefits to costs. Unlike CEA and CUA, which define costs and effects by comparing at least two strategies and choosing one as the winner, a CBA estimates the absolute monetary benefit of a proposed health care intervention or program. A key characteristic of a CBA performed in the field of health care is the need to assign monetary values to health outcomes. Such an exercise is considered controversial by some due to the placement of monetary value on human life (4).

Methods for Development of a Health Economic Decision Model

This section will address specific methods used in the development of a health economic decision model, with an emphasis on the two most common types of models, CEA and CUA.

Define the model's perspective The perspective of a health economic model is the first important consideration as costs are calculated differently based on the perspective taken. Most CEAs are performed from a third-party payer or a societal perspective. In a third-party payer perspective model, costs assumed by an insurance company or by Medicare are incorporated. These may include professional fees for encounters and procedures, reimbursements to the hospital or ambulatory surgical center for postoperative care, or reimbursements for home health or rehabilitation care. A societal perspective is usually most appropriate as it accounts not only for all costs included from a third-party payer perspective, but also costs related to a patient's lost productivity and the caregiver's expense. For example, if one surgical approach results in a faster return to work, this will be associated with less cost that is due to lost productivity. Use of the societal perspective has led to the recognition that minimally

invasive surgery results in cost savings to society (7,9,10). Other perspectives of health economic models include the *patient* and *hospital* perspectives. A hospital perspective model might be used to inform the decision to purchase expensive equipment such as robotic surgery platforms or an intraoperative radiotherapy facility.

Define the question Once the model's perspective has been determined, the clinical problem, standard approach, and any alternatives must be defined (11). The alternatives to the intervention of interest should always include a standard of care approach or even a "do nothing" approach. Next, a conceptual model for the analysis is developed, which outlines the possible consequences of each intervention. Decision models are often used as the conceptual framework for CEAs and have become an integral part of CEA studies.

Develop a decision tree A simple decision tree begins with a *decision node* representing the primary clinical decision being examined. Two or more strategies may be examined using one decision tree. The subsequent nodes in the tree are termed *chance nodes*, and define the probability of each possible clinical event that follows from the initial decision. For example, if the decision node concerns the clinical question of whether to accept a blood transfusion, the first chance node may define the probability that the patient will be infected with a blood-borne infection such as HIV if she accepts. Another chance node may define the risk of death if transfusion is refused (Fig. 18.1). Probabilities defined at chance nodes are usually derived from the literature or from clinical trial data. At the end of each branch of a decision tree is the *terminal node*, at which a payoff representing the effectiveness of that strategy occurs. In the blood transfusion example, the terminal nodes define 3 states: Life, death, or life with a blood-borne infection such as HIV. The payoff for life is 1, for death is 0, and for infection is a utility representing a lifetime spent with the infection. The expected value of each strategy, or its effectiveness, is calculated as the weighted average of the probabilities and payoffs associated with each terminal branch of the tree. The strategy resulting in the highest expected value is said to be the most effective. The payoff in an oncology model is usually expressed as a survival time. In a CUA, the effectiveness might be the product of survival time and the quality of life-based preference score, or utility.

Once all possible clinical events and their probabilities and payoffs have been defined by chance nodes, the costs of tests, treatments, and adverse events may be incorporated at each node. The cost associated with each strategy is calculated as a weighted average of the costs and probabilities associated with each branch of the tree.

Analysis of model After cost and effectiveness information have been collected and incorporated into the model, the analysis is performed. Results of cost-effectiveness models are expressed in terms of a comparison of 2 or more strategies. When one strategy is both more costly and less effective than an alternative strategy, it is said to be *dominated* and should not be considered. Likewise, a strategy that is both more effective and less costly is considered to be *dominant* and should be the treatment of choice. In these 2 cases, numeric cost-effectiveness quantification is not needed. When one strategy is both more costly and more effective than an alternative, an ICER is calculated. This is expressed as the difference in the mean cost divided by the difference in the mean effectiveness between strategies.

The ICER for comparison of intervention A compared to intervention B is defined as:

$$\frac{\text{Cost}_A - \text{Cost}_B}{\text{Effect}_A - \text{Effect}_B}$$

FIGURE 18.1. Simple decision tree representing the choice to accept or refuse a blood transfusion for severe anemia. The blue square is the decision node, green circles are chance nodes, and the red triangles are terminal nodes. Probabilities of events are depicted beneath each branch. Payoffs are listed to the right of terminal nodes. Three parameters are modeled as variables and have been given numeric values defined beneath the decision node. pHIV is the probability of being infected with HIV should the patient accept a transfusion. pDieWithoutTransfusion is the probability of death from severe anemia without a transfusion. Utility is the quality-of-life-related value of living with HIV, where 0 represents death and 1, perfect health.

It is important to note that the ICER is *not* estimated by dividing the cost of one intervention by the measure of its own effectiveness. This average cost-effectiveness ratio is not comparable to the ICER and is not a useful metric in cost-effectiveness analyses (12).

In the United States, an intervention has traditionally been considered cost-effective relative to an alternative strategy if the ICER is less than \$50,000 per quality-adjusted life year (QALY) (6). While ICER thresholds of \$50,000 per QALY are theoretically used in decision making, they are not strictly applied. Social norms may raise this value such that interventions costing up to \$100,000 or even greater per QALY have sometimes been considered cost-effective (13). The term “cost-effective” does not mean that a strategy saves money but rather that the additional cost of the intervention is worthwhile, usually from the perspective of society.

Sensitivity Analyses

Uncertainty in health economic analyses may exist about such input parameters as cost, survival, or clinical probabilities. To assess the impact of such uncertainty on the findings of a decision model, a sensitivity analysis can be performed. The simplest form of sensitivity analysis is a one-way analysis. Estimates are varied one parameter at a time to evaluate the impact made by the changes on the outcome or conclusions of the model (14). For example, in the simple model describing the decision to accept or refuse a blood transfusion, varying the probability of death due to anemia or the utility related to quality of life with HIV has an impact on the expected value of each decision (Fig. 18.2A–B). Likewise, a two-way sensitivity analysis can be performed to evaluate the impact of varying two model parameters simultaneously (Fig. 18.2C). When variation in the key parameters of a model over their confidence intervals or expected range of values does not change the model’s results, the model is said to be insensitive to these variations and its conclusions can be more strongly interpreted. Models whose outcomes change significantly when key estimates are varied over a clinically reasonable range should be interpreted with caution.

Most clinical models are fairly complex and may warrant the use of multiple simultaneous sensitivity analyses. In a Monte Carlo probabilistic sensitivity analysis, each variable in the model can be sampled from a probability distribution representing its value (15). Sampling parameter values from probability distributions (rather than from a simple range of values) places greater weight on likely combinations of parameter values.

Multiple sampling simulations of the model may then be run, each of which results in an individual cost-effectiveness comparison or estimate. Multiple simulations allow for construction of a cost-effectiveness scatterplot and the ability to express confidence intervals around the ICER estimate (Fig. 18.3), which effectively allows quantification of the total impact of uncertainty on the model and the confidence that can be placed in the analysis results.

INPUT DEVELOPMENT FOR HEALTH ECONOMIC MODELS

The following section details methods for the development of input data for health economic models.

Estimation of Costs

Cost definitions The costs incorporated into a CEA depend on the study’s perspective. The standard CEA or CUA is performed from a societal perspective (6). However, alternative perspectives include those of the patient, hospital, or a third-party payer. In a societal perspective analysis, the costs included are all of those borne by society and should therefore include both direct and indirect costs. Direct costs include direct medical costs (e.g., professional and hospital costs, diagnostic tests and procedures) and direct nonmedical costs (such as travel to receive care). Indirect costs account for lost productivity due to time off work for illness, both for the patient and any caregivers. When a health economic model is performed from a non-societal perspective, the scope of the costs included may be narrower. For example, in an analysis performed from a third-party payer perspective, lost productivity would not be included.

Which costs to include When developing a model to compare two strategies, it is important to remember that all medical costs do not necessarily need to be incorporated if it can reasonably be assumed that they do not differ between strategies. For example, for a comparison of 2 alternative surgical approaches to a disease, the cost of identical preoperative evaluation and laboratory testing need not be incorporated. Likewise, for a cost comparison of a Phase III clinical trial, the costs and consequences of adverse events that do not differ significantly between treatment arms may be omitted. Conversely,

FIGURE 18.2. **A.** One-way sensitivity analysis on the probability of death from anemia without a blood transfusion. When the probability of death from anemia exceeds the threshold value of 0.2, the expected value (EV) of accepting the transfusion exceeds that of refusing transfusion and the correct choice is to accept the transfusion. **B.** One-way sensitivity analysis on the quality-of-life-related utility of living with HIV. When the utility exceeds the threshold value of 0.9, the expected value (EV) of accepting the transfusion exceeds that of refusing transfusion and the correct choice is to accept the transfusion. **C.** Two-way sensitivity analysis in which the utility associated with HIV infection and the probability of death without transfusion are varied simultaneously. The blue shaded area represents values for which acceptance of a transfusion results in the highest expected value (payoff) and is the preferred choice. Green shaded area represents combinations for which refusal of transfusion is the preferred choice.

FIGURE 18.3. Cost-effectiveness scatterplot resulting from a Monte Carlo probabilistic sensitivity analysis for a model comparing intravenous carboplatin/paclitaxel to intraperitoneal cisplatin/paclitaxel and intravenous paclitaxel for advanced ovarian cancer. The simulation was repeated 10,000 times with sampling of key model parameters (cost, survival, and probability of adverse events) from probability distributions. This simulation resulted in an estimate of 95% confidence intervals to surround the primary incremental cost-effectiveness ratio estimate.

Cost effectiveness of intraperitoneal compared with intravenous chemotherapy for women with optimally resected stage III ovarian cancer: a Gynecologic Oncology Group study. *J Clin Oncol*. 2008;26(25):4144-4150. (114)

Abbreviation: CE, cost-effectiveness; QALY, quality-adjusted life year.

if there are global downstream effects on health care costs that result from an intervention, such as fewer subsequent hospitalizations or emergency department visits, these should be incorporated.

Costs versus charges When performing a health economic analysis, it is important to distinguish costs from charges. Charges represent what the provider or hospital asks an individual to pay for a service, and not the reimbursement provided by either a private third-party payer or Medicare. Because reimbursements by the CMS are generally considered to approximate the cost of providing a service, it is standard to use national Medicare reimbursements to approximate the costs of medical tests, procedures, or services in a health economic analysis (16). If a Medicare reimbursement is not available for a particular aspect of medical costs, charges may be used to calculate costs using a cost-charge ratio. Cost-charge ratios allow a calculation of the proportion of hospital charges that represent cost to the hospital. Cost-charge ratios are specific to individual hospital departments and may be available from CMS (<http://www.cms.gov>).

Surgical costs Health economic analyses in gynecologic oncology may include an estimate of the costs of surgical procedures. CMS reimbursements may be used to approximate these costs from a societal perspective. Direct surgical costs include professional fees (surgeon, anesthesiologist, and pathologist), the cost of hospital recovery, and the costs of any tests or procedures performed in the postoperative period. Postoperative outpatient care is usually part of a global fee that includes the first 90 days of postoperative care, and is therefore not included separately. Likewise, the reimbursement for recovery in the hospital or ambulatory surgery center is usually determined by a CMS code, and this reimbursement covers tests and inpatient care. However, additional procedures performed postoperatively are associated with additional professional fees.

Costs of hospitalization The cost of a hospitalization may be estimated for health economic models using the Diagnosis Related Group (DRG), a CMS code that takes into account the primary diagnosis and the patient's comorbidities, and is used to determine the reimbursement Medicare provides to the hospital. An alternative method for estimating the cost of an inpatient hospital stay is to use the AHRQ's Healthcare Cost and Utilization Project (HCUP) Nationwide Inpatient Sample (NIS) (<http://www.hcup-us.ahrq.gov/>). This large all-payer public database provides inpatient data from a national sample of over 1,000 hospitals in 44 states and is released annually. Mean and median charges and costs of all hospitalizations for a specific primary or secondary diagnosis can be obtained by entering ICD-9 codes. Results can be stratified by demographic information.

Outpatient treatment costs Outpatient treatments in gynecologic oncology often refer to chemotherapy. Cost tabulation should include the CMS reimbursements for the individual chemotherapy drugs and any other medications infused based on the designated J code for each drug. Tests performed routinely over the course of a cycle of treatment should also be included. Finally, the costs of infusion at an outpatient facility should be included using appropriate CPT codes.

Adverse events When 2 or more strategies are compared using a health economic model, it is critical that the adverse events associated with each strategy be accounted for. Specifically, when severe adverse events result in additional medical or nonmedical costs, these costs should be incorporated as well. For example, if one chemotherapy strategy results in a higher

rate of febrile neutropenia, the cost of a hospitalization for this diagnosis should be incorporated into the cost of each strategy in proportion to the probability of the event in each treatment group. Adverse events whose frequencies are not significantly different between strategies or that do not generate additional cost (e.g., grade 1 anemia) may reasonably be omitted from a CEA. However, models should adjust for quality of life differences resulting from adverse events.

Cost collection as a component of Phase III trials While many cost-effectiveness studies are performed following completion of the clinical trials from which the data is derived, such analyses are ideally planned and executed in conjunction with prospective Phase III trials. The International Society for Pharmacoeconomics and Outcomes Research (ISPOR) Task Force on Good Research Practices recommends that collection of health economic data should be fully integrated into Phase III studies (16). In a Phase III trial, prospective economic data is usually collected by accounting for differences in health resource utilization between treatment groups. Ideally this might include an accounting of all health-related encounters in each treatment group. However, logistical considerations during trial planning often require prioritization as to which data elements will be collected. Therefore, it is often appropriate to choose to focus on "big ticket" items as well as resources that are expected to differ between treatment arms. Resource utilization collection is accomplished by means of subject diaries in which outpatient and inpatient encounters as well as travel and caregiver time may be recorded. Once resource utilization collection is accomplished, national fee schedules and reimbursements are generally used to assign costs to each element.

Modeling Effectiveness

Effectiveness in CER should be reported in units of relevant clinical outcomes. For example, in oncology studies, effectiveness might be expressed as the number of cases of cancer prevented, the number of unnecessary surgical procedures avoided, or the number of cancer recurrences prevented. However, it is most common in oncology CER to quantify effectiveness using survival. Thus, in cost-effectiveness analyses the comparison of alternative strategies might be described in terms of the cost per additional year of life, or QALY, saved. While overall survival is a standard outcome in both CER and clinical trials, progression-free survival (PFS) may also be reported.

Modeling survival Survival outcomes may be modeled in several ways. One simple method is to assign a survival time (e.g., mean survival in years) to each relevant branch of a simple decision tree. While this method accomplishes the assignment of a survival "value" to each branch of the model, it does not account for additional costs or changes in quality of life that may need to be applied only to subjects who are still alive at a later time. For example, it may be useful to apply the cost of additional cycles of treatment or adverse events to only those individuals remaining alive or progression-free at a specific time point. An alternative, and more common, method is to use a modified Markov state transition model to represent survival (see the section *Construction of a Markov natural history model* below). When a modified Markov approach is used, costs of events that are applied only if a subject is alive or has relapsed may be applied at each relevant time point. Likewise, changes in quality of life during or after treatment may also be quantified. In the context of comparing effectiveness results of a prospective clinical trial, raw survival data can be used to model Kaplan-Meier survival curves directly (Fig. 18.4).

(114)

Modeling Quality of Life

Medical interventions in oncology may improve quality of life without extending life, or may extend life but worsen quality during treatment. Economic analyses that are based only on cost and efficacy do not fully account for the value of many treatments and interventions. CUAs account for the morbidity, physical well-being, and emotional well-being associated with medical treatments. CUAs may be used when the interventions being considered affect both quality of life and survival, or when there is no expected difference in survival but a difference in quality of life is anticipated (4).

In CUAs, quality of life is represented by a utility. A utility is a measure of the desirability or preference that individuals or societies place on a given health outcome (17,18). Utility scores are usually linked to judgments about the value of a particular health state. The anchor health states are 0 for death and 1 for perfect health. Applying utility scores to a cost-effectiveness model allows the outcome of the economic analysis, now the CUA, to be reported in QALYs.

Eliciting preferences for calculation of utility scores Use of utility scores in a cost utility model requires a defined health state for each distinct outcome of the intervention and its alternative (19). For example, health states of interest in ovarian cancer CUA may include: (a) newly diagnosed ovarian cancer starting primary chemotherapy; (b) completed primary therapy, no evidence of disease; (c) progressive disease on treatment; or (d) end-stage ovarian cancer. Descriptions of health states are needed for deriving utilities. The description of each health state includes information about levels of physical health, emotional health, activities of daily living, and overall well-being (20). Because psychological studies report that only a limited number of items can be simultaneously considered by an individual, it is recommended that each health state contain no more than 5 to 9 separate aspects (18,19). A rater provides preferences for each health state and a utility score is created.

Raters are selected according to the perspective of the study. For example, if a societal perspective is taken, then representatives of the population should be used to score the preference (6). The preferences of individuals with conditions of interest (such as patients) or of physicians are important ancillary information that might be incorporated into studies performed from alternative perspectives, but these cannot be substituted for societal preferences when the model's perspective is societal (11). Several rigorous formal approaches to the direct

measurement of preferences and calculation of utility scores for health states have been developed, of which the most commonly used are the standard gamble (SG) and the time-trade off (TTO) methods.

The *TTO* method presents the rater with a choice between 2 health states, both of which have a certain outcome (21). Raters choose between a set number of years of life in a certain health state (i.e., with disease) and a shorter number of years of life in perfect health. The shortest period of time in perfect health that a rater would accept in exchange for a lifetime in the diseased state determines the utility score. For example, if the rater would accept living the next 20 years (but no less) in perfect health instead of living the next 30 years in the diseased health state, the utility score for the health state would be 20/30 or 0.67. The *TTO* method is relatively easy for raters to comprehend.

In the *SG*, raters are asked to choose between two alternatives: one with a guaranteed outcome, and an alternative containing uncertainty or a “gamble.” The guaranteed outcome is the less-than-perfect health state that is being rated. The alternative consists of a treatment that has 2 possible results: Perfect health, with a probability of p , or a worst state (such as death) with a probability $1-p$. The value of p is then varied until the rater is indifferent between the choices of the alternative outcome (Fig. 18.5). Visual aids are often used to help the rater understand this exercise, but even with visual aids, some raters have difficulty thinking in terms of probability (19). While there is some debate concerning consistency of results between the *SG* and *TTO*, they are both considered standard methods to elicit utilities (18,19,22).

A simple *visual-analog scale* (VAS) is sometimes used to determine preferences for health states. A rater is shown a line with the anchor states (death, perfect health) at either end. The rater places a mark on this line to demonstrate a preference for the health condition being described. The utility is calculated as the position of the mark on the line divided by the length of the line. Although easy for raters to understand, this method is not “preference-based” due to the lack of the notion of sacrifice that is inherent in the *SG* and *TTO* methods (23). The validity of the visual analog method has therefore not been established, and these scales are only moderately correlated with the results from the *SG* and *TTO* methods (11).

Use of quality of life instruments and health status classification systems to derive utilities for comparative effectiveness research Measuring preferences for health outcomes using the direct *SG* and *TTO* methods is not a simple exercise and is beyond the scope of most clinical trials for which a CUA might be desirable. There exist a number of prescored health status classification systems to allow indirect assignment

FIGURE 18.5. Schematic describing the standard gamble method to elicit preferences for health states for incorporation into health economic models. “ p ” is the probability that the proposed treatment will result in restitution of perfect health that will last for the remainder of the subject's lifetime.

of utilities based on questionnaires, and calibrated using prior studies of societal preferences. Several of these indirect methods for eliciting utilities are described below.

Health utilities index (HUI) is a family of generic health profiles and preference-based systems that measure health status, report health-related quality of life, and produce utility scores. In the commonly used HUI mark 3 classification systems, attributes for which ratings are provided are vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain. In the multi-attribute approach used for HUI, a respondent completes a questionnaire providing information about her health status that is then scored using a multi-attribute scoring function derived from community preference measures for health states (24). While the HUI is considered a highly valid approach for deriving utilities, it has seldom been used in gynecologic cancer clinical trials.

EuroQoL-5D (EQ-5D) is a simple questionnaire in which raters report no problem, some problem, or a major problem in 5 dimensions: mobility, self-care, usual activities, pain/discomfort, and anxiety and depression (25,26). The ratings are scores from 0 (dead) to 1 (perfect health) and have been measured against the TTO technique on a random sample of 3,000 members of the adult population in the UK (27). The score obtained from the EQ-5D may be directly applied to health economic models and is the method preferred by the UK NICE.

Short form-6D (SF-6D) is a utility instrument based on responses to the longer and widely used SF-36 and SF-12 quality of life questionnaires (28,29). The classification system is based on physical functioning, role limitations, social functioning, pain, mental health, and vitality. The scoring model used for the SF-6D was developed based on the standard gamble utility measurements using a random sample of the UK general population. A scoring table is used to compute utilities from questionnaire responses (4).

Functional assessment of cancer therapy (FACT) is a 33-item scale developed to measure quality of life in patients undergoing cancer treatment (30). It is commonly used in RCTs conducted by the Gynecologic Oncology Group (GOG). The FACT consists of a core instrument (FACT-G) that can be supplemented by various subscales based on the malignancy of interest. While conversion of FACT scores to utilities has been studied (31,32), these methods have not been fully validated. Recent data from the GOG has further evaluated the ability to convert FACT scores to utilities in patients with ovarian cancer, arguing for a prospective trial attempting to address this issue [Hess LM, Brady WE, Havrilesky LJ, Cohn DE, Monk BJ, Wenzel L, Cella D. Comparison of methods to estimate health state utilities for ovarian cancer using quality of life data: A Gynecologic Oncology Group study. *Gynecol Oncol*. 2012 Oct 30. pii: S0090-8258(12)00851-7. doi: 10.1016/j.ygyno.2012.10.024. [Epub ahead of print]]

To date, the TTO and SG methods are the most accepted methods to develop utility scores. While the use of quality of life instruments eases the labor-intensiveness of collecting preferences using the TTO and SG methods, many question the validity of the use of indirect methods such as quality of life instruments to construct CUAs. At present, there is no clearly superior method for determining utility scores either directly or indirectly. Moreover, some believe that utilities should best be derived from patients as they best know their disease condition (33). Others feel that the preferences of the general public are most relevant because society as a whole must delegate distribution of its health care resources (34). As economic analyses evolve, the limitations of preference ratings should be examined and a consistent method of developing utility scores should be determined to allow for better comparisons to be made across cost-utility studies.

COMPARATIVE EFFECTIVENESS OF SCREENING FOR GYNECOLOGIC CANCERS

In the following section, methods for development of cancer natural history models and their use in screening decision analyses will be described. The current state of evidence for cervical and ovarian cancer screening as informed by comparative effectiveness research will then be reviewed.

Modeling the Natural History of Cancer

To evaluate the comparative effectiveness of a proposed cancer screening test for which no Phase III clinical trials have been completed, a model must be created that simulates the natural history of the disease with and without screening. The simplest model is a decision tree. Although decision trees are useful for modeling outcomes that occur over a short period of time, they can become unwieldy when trying to model a disease that occurs over a longer period or that involves recurrent events such as multiple episodes of screening or multiple cycles of treatment. Consider the decision to perform cancer screening on a woman with a family history of *BRCA1/2* mutation. A decision tree could be used to model her likelihood of developing breast or ovarian cancer by 15 years or of dying from another cause over that same time period, but this will not tell us when the woman developed cancer during the given time period, information that may impact the total cost of her care. Another type of model is usually needed to address issues of time dependency when modeling cancer. Markov models are used for events that recur or occur in a predictable manner over time (35). They are particularly well suited to depicting the events associated with cancer, especially cancers that have a screening component.

Construction of a Markov natural history model For creating a Markov model, the natural history of a cancer is broken up into a defined, mutually exclusive, and exhaustive set of states. For cervical cancer, these states would include: well, human papillomavirus (HPV) infection, preinvasive disease, undetected invasive cancer (Stages I through IV), detected invasive cancer (Stages I through IV), cancer death, and death from other causes. For epithelial ovarian cancer, which does not have a universal preinvasive state, natural history states might include: well, undetected and detected invasive cancer (Stages I through IV), cancer death, and death from other causes (Fig. 18.6). Once the states have been defined, movement (usually referred to as “transition”) between the states is defined based on knowledge of the cancer’s natural history. For example, a woman cannot enter Stage II cervical cancer without first having been in Stage I. The arrows in Figure 18.6 depict allowed transitions between states that have been defined for an ovarian cancer natural history model (36). Once the states and allowed transitions have been identified, probabilities of moving from one state to another over a fixed period of time are needed to populate the model. During each “cycle” of the model, allowed transitions between states occur. The cycle length of the model is a time period chosen to correspond to a period that takes into account the natural history of the disease as well as the timing of screening, diagnosis, and treatment recommendations. For most cancers a year is sufficient, although shorter or longer time periods can be used. The probabilities corresponding to the chosen time period for the model (referred to as a Markov cycle) are usually obtained from the epidemiologic literature, an analysis of an epidemiologic study, or expert opinion. Together, the states, allowed transitions, and probabilities constitute the model. Once programmed, the model can be used to calculate different outcomes. Usually, the outcomes are calculated for a cohort

FIGURE 18.6. Influence diagram for models of the natural history of ovarian cancer. Arrows represent allowed transitions between health states. Diamonds represent terminal states.

Source: Reprinted with permission from Havrilesky LJ, Sanders GD, Kulasingam S, et al. Development of an ovarian cancer screening decision model that incorporates disease heterogeneity: implications for potential mortality reduction. *Cancer*. 2011;117(3):545–553. (36)

(or cohorts) of women who are assumed to enter the model at a given age and then followed until death or a later age (i.e., 100 years).

Calibration An important step in developing a model is obtaining probabilities or estimates for key variables (referred to as parameters) from the literature. However, often there are few available estimates, estimates of varying degrees of quality, or even no existing estimates for a given model parameter. The selection of a given clinical estimate is important since this affects the credibility of the model's aggregate result. Calibration is a process that involves comparing the model-predicted results to observed data to ensure a reasonably good fit of one to the other. Model calibration involves several steps: (a) identification of calibration endpoints (for cancer this usually means age-specific cancer incidence, but can also include stage distribution and age-specific mortality curve); (b) establishment of criteria for determining how well the model-predicted data fit the observed data. This may be visual inspection or use of a statistical goodness of fit test; (c) adjustment of the set of model input parameters (i.e., probabilities); and (d) comparison of model-predicted outcomes to observed outcomes using the pre-specified criteria and repeating steps 3 and 4 until a satisfactory calibration is achieved (37).

Figures 18.7 and 18.8 show the calibration results for 2 models (ovarian and cervical) that used visual inspection to achieve calibration (36,38). Another calibration method uses goodness of fit statistics and then selects parameter sets that best fit the observed cancer incidence curve. This latter method improves upon visual inspection in a few ways: (a) the calibration goal is formally stated, which can aide with reproducibility and (b) instead of one good fitting set, multiple sets are used, which can account for parameter uncertainty (39).

Validation Model validation (confirming that a calibrated model predicts results that are consistent with observed results from screening trials) can be achieved in a number of ways. The most robust method is to compare model-predicted outcomes with actual outcomes. For example, Havrilesky et al. constructed a natural history model accounting for the observed heterogeneity of epithelial ovarian cancers. Validation was performed by simulating the published prevalence phase of the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) by entering the age and prevalence of disease from the trial population as well as the reported sensitivity and specificity of the trial's multimodality screening algorithm. The model predicted the stage distribution of cancers detected by screening and the positive predictive value of the multimodality prevalence screen within their reported 95% confidence intervals (36). To the degree that simulated results do not reproduce those observed in a clinical trial, the question arises whether there are key input parameters or model structural differences that affect the conclusions. A model can then be revised to determine whether the prediction is improved in an iterative process. Usually, the initial decision to conduct a modeling study is based on the fact that there are no observed data that exist to answer a given question. In this case, model validation is achieved by comparing the results from models built by different, independent groups, to evaluate for similarity. This approach has been adopted by Cancer Intervention and Surveillance Modeling Network (CISNET). CISNET is a consortium of National Cancer Institute (NCI)-sponsored investigators that uses statistical modeling to study cancer control interventions in prevention, screening, and treatment and their effects on population trends in incidence and mortality. The models in this consortium were independently developed and have been calibrated to US data. The U.S. Preventive Services Task Force has used the results from modeling studies conducted

FIGURE 18.7. Calibration of ovarian cancer natural history model on the age-related incidence of ovarian cancer in the US. *Blue line* represents model output; *red dots* represent SEER data.

by this group to inform their recommendations for colorectal and breast cancer (40,41).

Simulation of Screening

The impact of screening, diagnosis, and treatment can be tracked using a Markov model. Markov models can be programmed to keep count of the outcomes associated with diagnosis, treatment, and screening. Examples include the average number of false-positive or false-negative screening test results, the number of diagnostic procedures such as colposcopy or laparoscopy performed, number of preinvasive lesions detected, and treatments.

Other important outcomes include cancer incidence, stage distribution, and mortality. If the cohort of women is modeled over a sufficiently long period of time, the model can be used to calculate life expectancy, lifetime costs, and quality-adjusted life expectancy.

Cervical Cancer

For cervical cancer, modeling has played a particularly prominent role in informing decisions regarding which screening and triage tests to adopt, how frequently women should be screened, and whether the addition of vaccination to screening is cost-effective. This prominent role is due to the fact that trials of new screening

tests include follow-up and treatment that often differ from clinical practice, or are conducted in non-US populations with different screening histories. Modeling studies can also be used to project both short- and long-term results from trials. For example, trials for the HPV vaccines used cervical intraepithelial neoplasia (CIN) grade 2 or higher as primary outcomes. However, cancer incidence and death are more important outcomes for policy makers. Modeling has been used to estimate the potential cost-effectiveness of adding vaccination to screening. More recently, modeling has been used to justify the expanded coverage of HPV vaccines to include boys. The following sections describe how natural history models of HPV and cervical cancer are constructed, and how such models have been used to inform policies regarding screening and vaccination for cervical cancer prevention.

Natural history of cervical cancer Natural history models have primarily used the CIN nomenclature to characterize progression from HPV infection through preinvasive disease to invasive cancer. CIN 1 is usually modeled as a separate category from CIN 2 or 3, to reflect the general consensus that this lesion represents a self-limited infection that has a high likelihood of spontaneously regressing. However, while some have combined CIN 2 and 3 into a single category (42–47), others have separated these 2 categories (48–50). Separating CIN 2 and 3 in modeling is based on the findings of a large trial that suggested that CIN 2 may be a self-limited lesion, especially in young women (51). Moreover, ongoing and recently completed trials examining the potential role of HPV DNA testing in screening have chosen CIN 3 as the surrogate endpoint for cancer (52). By separating CIN 2 and 3, these models are able to predict the extent to which the detection and treatment of CIN 3 will lead to reductions in cancer incidence and mortality.

Until recently, models have based progression and regression rates between the different states on estimates that were averaged across different HPV types (53). However, models that can quantify the impact of type-specific infection have now been developed, prompted by several factors: (a) the availability of HPV vaccines that are targeted at a few HPV types; (b) the U.S. Food and Drug Administration approval of type-specific HPV tests; and (c) guidelines that allow for triage to immediate treatment based on type-specific HPV infection. These more recent models have stratified progression and regression between different CIN states by HPV type. For example, Sanders and Taira grouped HPV into low- and high-risk types (54), Goldie et al. grouped HPV into low-risk, high-risk, and HPV 16 and 18 (55), and Elbasha et al. modeled 4 HPV types only: HPV 6, 11, 16, and 18 (50). A more recent model by Kim and Goldie (2008), designed to assess vaccine strategies in the US, stratified HPV infection by HPV 16, HPV 18, and other high-risk and low-risk types (56,57). Of note, to assess the potential impact of vaccines with more HPV types than those currently available, Brisson et al. have further stratified an HPV model using 18 HPV types. As our understanding of the natural history of each type grows, HPV type-specific testing is becoming more common and vaccines are being expanded to include additional HPV types. In this changing environment, models will need to further stratify by HPV type to better predict the expected benefits and harms of type-specific testing and vaccination.

Questions Addressed by Cervical Cancer Models

Appropriate age to begin/end and screening interval with cytology A mathematical model of cervical cancer, developed in the 1980s by David Eddy, was used to examine the relationship between screening interval using Pap smears and cancer incidence (58). This modeling study showed that screening every 2 or 3 years would result in 95% to 99% of the cancer reduction benefit of screening every year, but with lower costs and fewer procedures.

In terms of the age to begin and end screening, these have for the most part been based on epidemiologic data showing that cancer incidence peaks in the late 30s to mid-40s, but that the incidence of CIN peaks in the 20s. Given this, guidelines have usually called for screening in the late teens and early 20s, although there has been a shift toward a recommendation to begin screening in the 20s in more recent years (59,60). Canfell et al. modeled the impact of changing the UK screening guidelines to begin at 25 years of age, instead of 21 years (61). They found that if the age to start screening was delayed until 25, the lifetime risk of cancer would be minimally affected (cumulative lifetime incidence decreasing from 0.63% to 0.61%) due to the low incidence of cancer in young women (61). More recently, Kulasingam et al. modeled the impact of varying the age to begin screening in 1-year increments from age 15 years to age 25 years on cancer incidence and mortality (62). They showed that screening in the teens was associated with a high number of additional diagnostic procedures and small reductions in lifetime risk of cancer compared to delaying screening until the 20s. In terms of the age to end screening, Canfell et al. showed that further reductions in lifetime incidence of cancer (from 0.63% to 0.56%) could be achieved if screening were extended from age 64 to 79 and conducted at 5-year intervals (61). Kulasingam et al. estimated the impact of continuing to screen women who had been screened every 3 years since age 21 beyond age 65 years, and showed small incremental reductions in cancer but large increases in additional procedures (62). Although the differences in conclusions between the 2 modeling studies are presumably due to differences in screening intervals modeled, other differences that may play a role include benign hysterectomy rates, deaths from other causes, or cohort effects in screening. Importantly, these studies illustrate how modeling can be used to examine issues related to age that epidemiologic studies may not be able to answer.

Liquid-based cytology versus conventional cytology

Models are particularly useful for predicting the impact of the adoption of new screening tests or treatments on cancer incidence and mortality. However, model conclusions are heavily dependent on the quality of the data used to inform key parameters such as test sensitivity and specificity. An example is the modeling that compared the cost-effectiveness implications of conventional cytology smears to liquid-based cytology smears (63,64). These early studies used estimates of test accuracy from nonrandomized studies. These studies suggested that liquid-based cytology had a higher sensitivity and comparable specificity to conventional cytology. As a result, adoption of liquid-based cytology for cervical cancer screening in the U.S. was predicted to be cost-effective compared to screening with conventional cytology. More recently, however, RCTs and meta-analyses have concluded that there is no significant difference in test performance between liquid cytology and conventional cytology (52).

Use of HPV testing in screening A number of randomized trials (both ongoing and recently completed) have shown that HPV DNA testing is more sensitive but less specific than cytology for detection of CIN 3+ (52). A number of studies have examined the cost-effectiveness of adding HPV DNA testing (with either PCR-based tests or hybrid capture 2) to screening programs (65). Strategies examined include co-testing (simultaneous testing with both cytology and HPV DNA, with referral for treatment if either is abnormal), primary testing with HPV followed by triage using cytology if the HPV DNA test is abnormal, primary testing with HPV only, and primary testing with cytology followed by triage using HPV DNA for those with abnormal cytology results. Across a range of settings, these studies suggest that the cost-effectiveness of adding HPV DNA to cytology-based screening depends on whether the interval between screening tests can be increased as well as the follow-up for women with discordant test results.

Of the different HPV and cytology strategies that have been compared for cost-effectiveness, one strategy in particular shows promise across a range of analyses and settings. HPV DNA testing followed by triage based on cytology for women with positive HPV results has been identified as a potentially cost-effective strategy compared to both cytology alone and the co-testing strategies (66,67). This strategy, which uses a sensitive test first (HPV), followed by a specific test (cytology), allows one to maximize detection of high-grade disease, while potentially minimizing false-positives, thereby reducing the costs of screening. Results from ongoing trials, such as the HPV-FOCAL trial in Canada, which has recently reported preliminary validation of this strategy, will be needed to confirm whether the modeling predictions are correct (68).

Quantifying the impact of HPV vaccination Two types of models have been used to explore HPV vaccine effectiveness: Markov state transition cohort models (described above) and dynamic transmission models, with a third category – hybrid models – that use a combination of the two (69). Dynamic models track population changes over time by taking into account births as well as deaths. Importantly, dynamic transmission models also explain how infection with HPV depends on patterns of sexual behavior and the distribution of infection in the population (70). As such, a strength of dynamic models is that they can be used to determine herd immunity, explore the relative value of vaccinating boys in addition to girls, and explore how sexual mixing patterns (how men and women form partnerships and how these affect transmission) affect the age at which vaccination should begin and age(s) for catch-up programs (i.e., vaccination offered to girls and/or women who are not part of the optimal age group but who may still derive a benefit). These indirect effects are not captured by Markov models; as a result, Markov models may underestimate the effect of vaccination. Hybrid models use both approaches – generating HPV incidence under different vaccination scenarios from a dynamic model, which is then used as an input to the Markov model. A recent modeling study conducted using multiple, independently developed HPV and cervical cancer models concluded that vaccination of girls prior to the age of sexual debut has the potential to considerably reduce the burden of CIN and cervical cancer (71). This is especially true if a long duration of vaccine efficacy and high vaccine coverage are modeled. Vaccine price has also consistently been shown to impact the cost-effectiveness of adding vaccination to screening or adding HPV vaccines to existing vaccine programs. Indeed, if HPV vaccines are priced below certain thresholds for different countries, HPV vaccination could potentially be cost-saving compared to not screening (72). Of note, across a range of analyses, vaccination of girls only prior to onset of sexual activity, as opposed to vaccination of boys and girls plus catch-up vaccination, has been shown to have the most attractive cost-effectiveness profile. However, under conditions of low coverage, as has occurred in the US, extending vaccination to boys is potentially cost-effective (73). On the basis of these results, and survey data showing low uptake of the HPV vaccines in the U.S., the Centers for Disease Control and Prevention Advisory Committee on Immunization Practices decided to extend HPV vaccine recommendations to include boys in addition to girls (http://www.immunize.org/acip/acipvax_hpv.asp). In terms of which vaccine to use (bivalent or quadrivalent), modeling from the UK suggests that the bivalent vaccine (which is targeted at 2 carcinogenic HPV types, 16 and 18) would need to be less costly than the quadrivalent vaccine (which protects against the same HPV types, 16 and 18, as well as 2 types associated with >90% of genital warts) to be equally cost-effective (66,74).

Screening in the era of HPV vaccines The issue of whether and how screening should change in the era of HPV vaccines is complex and will depend on a number of factors that are

still unknown. These include, but are not limited to, the performance of cytology and HPV tests such as hybrid capture 2 that are not type-specific, whether predicted reductions in CIN and cancer are achieved, and whether vaccination will affect screening behavior, in particular, screening participation. Under the assumption that vaccines will markedly reduce cancer incidence and mortality, potentially cost-effective approaches to screening vaccinated cohorts of women include strategies that use a less frequent screening interval, delayed age of first screening, and/or use of a strategy based on HPV DNA testing followed by cytology (66,75). Preliminary modeling to examine the impact of cross-protection and broad spectrum vaccines (such as the Merck octavalent vaccine that is currently in early trials) suggests that far fewer screens than are currently recommended will be needed to achieve significant reductions in cervical cancer (76).

Modeling has been used extensively in cervical cancer to inform how we should approach screening and add HPV vaccination programs to screening programs. Given the development of new tests for cervical cancer and new vaccines that cover more HPV types than the first generation of HPV vaccines, modeling will continue to play a key role in determining the most effective and cost-effective strategies for prevention of cervical cancer.

Ovarian Cancer

Because the majority of ovarian cancers are diagnosed at an advanced stage, there has been considerable interest in designing screening strategies to diagnose and treat women earlier, in the hopes of improving survival outcomes. While screening for breast and colon cancer has been proven to reduce mortality, no screening test for ovarian cancer has yet been proven effective. Several key parameters may impact the success of any cancer screening program: (a) availability of effective treatment for screen positive individuals; (b) sufficiently high disease prevalence; (c) existence of an effective screening test; and (d) acceptable cost or cost-effectiveness of the screening program. Each of these parameters is addressed below in the context of development of a screening test for epithelial ovarian cancer.

Effectiveness of treatment Pathologic and genetic data now suggest that epithelial ovarian cancer is a heterogeneous disease, with a number of different precursor lesions. Many high-grade serous ovarian cancers likely originate in the fallopian tubes, while some clear cell and endometrioid lesions may originate in endometriosis. Because there is no universal, clearly defined precursor lesion for all epithelial ovarian cancer, the target lesion for the screening tests that are currently in Phase III trials is stage I disease. Targeting early-stage disease is appropriate because survival from epithelial ovarian cancer diagnosed at stage I is encouraging. Women with stage I disease with low-risk features may be cured without the need for adjuvant treatment, while those with higher risk stage I disease may still achieve excellent outcomes following 3 to 6 cycles of platinum-and taxane-based chemotherapy (77).

Disease prevalence Perhaps the biggest challenge to the development of a successful ovarian cancer screening program is the low prevalence of this disease. The lifetime incidence of ovarian cancer in the U.S. is approximately 1.4%. In postmenopausal women, the most likely target population for a screening program, its prevalence is approximately 40 per 100,000 women. Disease prevalence has a direct impact on the achievable positive predictive value of a screening test, which defines the number of diagnostic procedures or surgeries that would be required to diagnose one case of ovarian cancer. Expert opinion suggests that the minimal acceptable positive predictive value

for an ovarian cancer screening test should be 10%. To achieve this value in the postmenopausal population, a screening test needs to have a specificity exceeding 99.6%.

Effectiveness of screening test To date, no screening test for ovarian cancer has been proven effective in reducing mortality from this disease. Two large randomized trials have recently been performed to evaluate screening strategies utilizing the CA-125 serum test and transvaginal ultrasound. The Prostate, Lung, Colorectal, and Ovarian (PLCO) screening trial randomized 78,216 women to either usual care or a combination of annual CA-125 for 6 consecutive years and annual transvaginal ultrasound for 4 consecutive years (78). Follow-up of test results was determined by each subject's primary physician. After a median follow-up of 12.4 years, there was no difference in stage distribution at diagnosis of ovarian cancer (77%–78% stage III–IV) and no difference in ovarian cancer mortality between the screened and unscreened groups. However, there was evidence of possible harm due to the screening intervention, in the form of a 15% rate of serious adverse events among women with false-positive screening tests who underwent surgical procedures. The authors concluded that simultaneous screening with CA-125 and ultrasound does not reduce ovarian cancer mortality and may introduce harm (79).

A second large screening trial, the UKCTOCS study, randomized 202,638 postmenopausal women to no intervention, annual transvaginal ultrasound, or a multimodality algorithm incorporating annual CA-125 and second-line transvaginal ultrasound. In the prevalence round of screening, the multimodality screening algorithm had a sensitivity of 89.5% and specificity of 99.8% and resulted in a more favorable stage distribution than the no-intervention group, with over 47% of ovarian cancers diagnosed at stage I or II. While mortality results from this trial are pending, the authors concluded that the prevalence screen data were encouraging regarding the feasibility of this screening program (80).

Comparative effectiveness of screening Several groups have used mathematical modeling to determine the likely success and cost-effectiveness of screening strategies. Skates and Singer designed the first reported stochastic simulation model of the natural history of ovarian cancer. This model, which assumed orderly progression from stage I to stage IV and estimated the mean time spent in stage I at 9 months based on the expert opinion of gynecologic oncologists, suggested that screening using CA-125 could potentially save 3.4 years of life per case of cancer detected (81). Urban et al. subsequently modified the Skates and Singer model and performed a cost-effectiveness assessment of several screening strategies. The authors reported that multimodality screening with CA-125 followed by transvaginal ultrasound only if CA-125 was positive or doubling was potentially cost-effective compared to single test strategies and no screening (82).

More recent screening models have incorporated new data about the pathophysiology and progression of ovarian cancer. Havrilesky et al. constructed a natural history model that, based on the physical proximity of the ovaries to upper abdominal organs such as small bowel and omentum, allowed progression of stage I cancers either to stage II or directly to stage III (83). Disease incidence, mortality, and stage distribution were calibrated to reflect Surveillance Epidemiology and End Results (SEER) data. A modified version of this model was designed to account for the heterogeneity of ovarian cancer by modeling aggressive and indolent phenotypes with different rates of progression (36). These models highlighted factors that are important to the success of a screening program. For example, increasing the frequency of screening had a more favorable impact on reducing cancer mortality than increasing the sensitivity of the individual screening test. However, due to the increased cost

of screening more frequently, increasing the frequency actually reduced cost-effectiveness. Both models reinforced the important link between specificity and positive predictive value. An annual screening test with a sensitivity of 85% and specificity of less than 99% would have a positive predictive value not exceeding 4%. However, at a specificity of 99.9%, the positive predictive value for annual screening was excellent at 22%. Annual screening of a population of women aged 50 to 85 years at average risk of ovarian cancer with a test at 85% sensitivity and 95% specificity was predicted to improve life expectancy 2.92 days on average, with an ICER of \$73,469/YLS compared to no screening. However, simulated screening of a “high-risk” population of women aged 50 to 85 years with a relative risk of developing ovarian cancer of 2 resulted in an improvement in the ICER to \$36,025/YLS when compared to no screening. In sensitivity analysis, key factors in achieving a cost-effective screening test (defined as an ICER of less than \$50,000/YLS) were an inexpensive test, a very high test specificity, and infrequent (annual or less) testing. Screening appeared to be potentially most cost-effective when the test specificity was well above 99% and the testing interval was annual or less frequently (83).

These prior models confirm that very high test specificity is required to achieve acceptable positive predictive values and that population-based screening may not be cost-effective in the form currently being evaluated in clinical trials. However, annual screening for ovarian cancer appears to be potentially cost-effective in high-risk populations and at very high screening test specificities. Both mortality data and final analysis of the costs of the multimodality screening algorithm in the UKCTOCS trial are critical to any assessment of the costs, benefits, and potential cost-effectiveness of currently available screening strategies. Moreover, because none of the health economic models of screening performed to date have taken quality of life into account, any health economic assessments of ovarian cancer screening would be premature.

Primary prevention in high-risk women Women who are carriers of genetic mutations in *BRCA1* or *BRCA2* are at markedly increased risk for ovarian cancer; the average risk of developing ovarian cancer by age 70 is 39% (95% confidence interval [CI], 18%–54%) for *BRCA1* mutation carriers and 11% (CI, 2.4%–19%) for *BRCA2* mutation carriers (84). Likewise, women with Lynch syndrome-associated *MLH1* and *MSH2* mutations have up to 20% (CI, 1%–65%) and 24% (CI, 3%–52%) risk, respectively, of developing ovarian cancer by the same age (85). Although the prevalence of genetic mutations predisposing women to ovarian cancer in the general population is low, the high risk of cancer among women who are mutation carriers underscores the importance of modifying their likelihood of developing cancer.

The choice of a risk-reduction strategy for women at elevated risk is an individual one and commonly includes screening strategies and prophylactic surgery. Unfortunately, screening high-risk women with available modalities has not yet proven successful (86–88). In a *BRCA1/2* mutation-carrying population, bilateral salpingo-oophorectomy (BSO) has been demonstrated to reduce the risk of ovarian, tubal, or peritoneal cancers by 80% and the risk of breast cancer by 50% (89). In addition, several groups have designed health-economic decision models demonstrating that prophylactic surgery is both effective and cost-effective in women at high genetic risk for ovarian cancer (90–93). However, surgical prophylaxis performed prior to menopause is accompanied both by potential harm and the certain premature loss of ovarian function and is not generally recommended in the general population (94,95). Despite the effectiveness of prophylactic BSO, some women at high risk prefer alternatives that are less invasive, do not result in early menopause, and preserve fertility. The GOG is currently completing a nonrandomized

prospective trial comparing longitudinal screening with CA-125 and ultrasound to risk-reducing BSO in a high genetic risk population (96). This trial includes both subsequent cancer diagnoses and quality-of-life assessments, and may be informative from a comparative effectiveness standpoint.

COMPARATIVE EFFECTIVENESS OF THERAPEUTICS IN GYNECOLOGIC CANCERS

The comparative effectiveness literature regarding therapeutic interventions for gynecologic malignancies is reviewed in the next section.

Ovarian Cancer

Chemotherapy for newly diagnosed ovarian cancer The standard treatment for ovarian cancer is primary surgical staging with maximum possible cytoreduction followed by chemotherapy. Intravenous chemotherapy usually consists of a taxane and a platinum agent for 3 to 6 cycles; patients with advanced intraperitoneal disease are often candidates for intraperitoneal chemotherapy (97). The addition of bevacizumab to primary chemotherapy followed by consolidation bevacizumab has been found to provide a short-term additional benefit in Phase III trials (98,99). Likewise, dose-dense paclitaxel was associated with clinical benefit in one Phase III trial and is now under investigation by the GOG (100). As novel chemotherapy regimens for primary treatment emerge, some consideration should be given not only to the number of months of survival benefit, but to the costs and effects on quality of life of each.

Introduction of taxanes The first cost-effectiveness studies in ovarian cancer chemotherapy were performed in response to the introduction of taxanes into the frontline chemotherapy regimen for this disease. Two independent RCTs, conducted by the GOG 111 and a European-Canadian Intergroup (OV-10), demonstrated that cisplatin plus paclitaxel as primary chemotherapy is superior to previous therapy of cisplatin plus cyclophosphamide in clinical response rate, progression-free survival, and overall survival (101–103). Three Phase III RCTs subsequently proved similar efficacy of paclitaxel in combination with either carboplatin or cisplatin for the adjuvant treatment of ovarian cancer (104–106). The carboplatin combination was better tolerated and has subsequently become a standard first-line treatment (107).

When first introduced, paclitaxel-cisplatin was a more expensive therapy than the old standard of cyclophosphamide-cisplatin. A number of cost-effectiveness investigations were performed using data from GOG 111, which compared cisplatin plus paclitaxel to cisplatin plus cyclophosphamide. From the perspective of a US oncology practice, the total drug costs for cisplatin plus paclitaxel were 4 times higher than those for cisplatin plus cyclophosphamide (US \$9,918 vs. US \$2,527; year of costing not specified) (108). Compared with cisplatin plus cyclophosphamide, the incremental costs per year of life gained for cisplatin plus paclitaxel therapy were US \$19,820 for inpatient treatment and US \$21,222 for outpatient treatment. These incremental costs fall well within the generally accepted cost-effective range for new therapies.

Several cost-effectiveness analyses examined the addition of paclitaxel to first-line therapy from the perspective of health systems outside the US. From a Canadian health system perspective, cisplatin plus paclitaxel had an ICER of CaD \$32,213 (1993 costs for drug and hospital costs) per life-year gained compared to cyclophosphamide-cisplatin (109). The investigators originally

concluded that it may not be possible to adopt this therapy as first-line for all advanced-stage ovarian cancer patients because it would cost the province of Ontario an additional CaD \$9 million a year. Berger et al. investigated the cost-effectiveness of cisplatin plus paclitaxel from the perspective of various European countries' national health services. The incremental costs of cisplatin plus paclitaxel per life-year saved were evaluated for Germany (US \$9,362), Spain (US \$6,395), France (US \$6,642), Italy (US \$11,420), the Netherlands (US \$7,796), and the UK (US \$6,403) (110).

Carboplatin and paclitaxel are now both marketed as generics, and therefore these prior studies are less applicable than when originally published. Given the current low cost of paclitaxel, any clinically superior regimen using this drug is also likely to be found cost-effective. Chan et al. have recently performed an economic analysis based on results of a Phase III Japanese GOG trial (100), demonstrating that weekly dose-dense paclitaxel is cost-effective compared to a 3-week regimen in the setting of primary treatment (111).

Intraperitoneal chemotherapy The NCCN Guidelines for ovarian cancer recommend intraperitoneal (IP) chemotherapy as primary/adjuvant therapy for optimally debulked (<1cm) stage II or greater ovarian cancer treatment (112). Three Phase III clinical trials have identified advantages to the use of IP chemotherapy for adjuvant treatment of stage III ovarian cancer (97,113,114). The most recent of these studies demonstrated an overall survival advantage of 16 months in the IP arm at the expense of increased risk of adverse events and a significant reduction in quality of life.

Two analyses have evaluated the cost-effectiveness of IP chemotherapy for the primary treatment of stage III ovarian cancer. When comparing IP to intravenous (IV) chemotherapy, Bristow et al. reported that IP chemotherapy was potentially cost-effective compared to IV, with an ICER of \$37,454 per QALY (115). Havrilesky et al. reported an estimate of \$180,022 per QALY when using a 7-year time horizon, which was consistent with the current duration of survival results from GOG 172 (116). However, when the time horizon was extended to a lifetime under the assumption that any survival advantage realized with IP chemo would persist over that period, the ICER of IP chemotherapy dropped to \$32,053 per QALY. Also of note, under the assumption that IP chemotherapy is equally effective as an outpatient regimen, the ICER of IP compared to IV chemotherapy becomes even more attractive. While both studies informally incorporated quality of life based on the FACT surveys administered to patients enrolled on GOG trials of chemotherapy, neither performed a validated utility assessment. Conclusions that may be drawn from these studies are that IP chemotherapy is potentially cost-effective for women with stage III disease, but that more formal incorporation of quality of life, longer term follow-up of the results of the last Phase III study, and investigation of less costly outpatient IP regimens would strengthen this conclusion (115,116).

Bevacizumab Bevacizumab is an anti-vascular endothelial growth factor (VEGF) inhibitor of angiogenesis and is FDA-approved for treatments of renal cell carcinoma, colorectal cancer, glioblastoma, and non-small cell lung cancer. The ICON7 and GOG 218 Phase III clinical trials of newly diagnosed ovarian cancer independently reported a small 2- to 6-month PFS advantage to the addition of bevacizumab to primary combination carboplatin/paclitaxel, followed by 14 to 22 additional cycles of consolidation bevacizumab in the absence of progression (98,99). Even prior to the initial presentation of this data in ovarian cancer, questions were raised about the cost of universal bevacizumab. Cohn et al. performed a cost-effectiveness analysis examining the likely clinical benefit of bevacizumab and the cost of the drug as well as its associated adverse events. This analysis demonstrated that there was no reasonable scenario

under which bevacizumab could be considered cost-effective by existing measures (117).

A subset analysis of the ICON7 data revealed that the main benefit appears to be confined to women with high-risk disease such as those suboptimally cytoreduced and those with stage IV disease (99). While, ideally, treatment of a smaller subset of women with ovarian cancer who are most likely to benefit would make this drug more cost-effective, initial attempts at modeling this scenario did not demonstrate this to be a cost-effective alternative (118).

Consolidation therapy Consolidation regimens that have been studied for ovarian cancer are paclitaxel and bevacizumab; both have proven PFS benefits but neither has demonstrated an overall survival benefit. Lesnock et al. performed a cost-effectiveness analysis of consolidation therapy following carboplatin/paclitaxel, comparing 12 months additional paclitaxel to 17 cycles of additional bevacizumab. Clinical data were derived from the PFS results of GOG 178 and GOG 218. Consolidation therapy with paclitaxel was found to be cost-effective, with an ICER of \$13,402 compared to no consolidation therapy. Bevacizumab consolidation was dominated (less effective and more costly) by paclitaxel consolidation. This study was performed prior to mature overall survival results of GOG 218 and the authors noted that a significant overall survival improvement would potentially improve the value of bevacizumab consolidation (119).

Chemotherapy for recurrent ovarian cancer Most women with ovarian cancer will achieve clinical remission following surgery and primary adjuvant chemotherapy. Unfortunately, the majority of patients eventually develop recurrent disease which is rarely curable (120). Patients who experience recurrence more than 6 months after completing a first-line chemotherapy regimen are considered to have “platinum-sensitive” ovarian cancer and have an excellent response rate when re-treated with platinum agents (121,122).

The optimal treatment of recurrent ovarian cancer is subject to ongoing debate and is affected by considerations of survival, toxicity, and quality of life. Patients with platinum-sensitive disease have a good response rate to re-treatment with platinum-based regimens; two large RCTs have compared the use of single-agent therapy with combination regimens for platinum-sensitive ovarian cancer. These studies identified a PFS advantage for the combination regimens of gemcitabine plus carboplatin and paclitaxel plus platinum chemotherapy regimens (as well as an overall survival advantage for paclitaxel plus platinum) compared to platinum alone, and the authors suggested that the combination regimens should be considered standard of care (123,124).

On the basis of these 2 studies, Havrilesky et al. designed a Markov state transition model that evaluated the optimal treatment strategy for patients with recurrent platinum-sensitive ovarian cancer. Paclitaxel plus carboplatin had an ICER of \$15,564 per additional progression-free year compared to single-agent carboplatin, while gemcitabine plus carboplatin has a less attractive ICER of \$278,388 per additional progression-free year compared to paclitaxel plus carboplatin (125). Given that both carboplatin and paclitaxel are now available as generic drugs in the US, their cost advantage is not surprising. Neurologic and hematologic toxicities of the regimens were incorporated into a sensitivity analysis that varied the severity and costs associated with treatment. Over a reasonable range of utility scores, paclitaxel plus carboplatin was still cost-effective compared to carboplatin alone, and gemcitabine plus carboplatin remained non-cost-effective (125). These results must be interpreted on an individual basis with an individual's prior adverse event profile in mind; for example, it is unlikely that a patient with severe neurotoxicity due to prior taxane treatment would be re-treated with the same drug.

Recurrent ovarian cancer that occurs within 6 months of completing a first-line chemotherapy regimen has a poor prognosis, with cure being very unlikely. Rocconi et al. performed a cost-effectiveness analysis of treatment options for recurrent platinum-resistant ovarian cancer and concluded that only best supportive care (no chemotherapy) was clearly cost-effective, while second-line monotherapy was possibly marginally cost-effective (ICER \$64,104/YLS) as well (126). Even without incorporation of toxicity rates and costs, the authors found that combination chemotherapy regimens were never cost-effective for platinum-resistant disease due to unfavorable ICERs.

Cervical Cancer

Primary treatment The standard treatment of cervical cancer has been established for very early-stage and locally advanced-stage disease. However, there is continued debate over the appropriate treatment of Stage IB2 disease (127). Current options include primary surgery with radical hysterectomy and lymphadenectomy followed by tailored chemoradiation, primary chemoradiation, or neoadjuvant chemotherapy followed by radical hysterectomy and tailored chemoradiation. The choice of therapy depends on many factors including available resources, costs, patient characteristics, and physician preferences.

Two groups have developed health economic models to inform the treatment of stage IB2 cervical cancer. Rocconi et al. developed a decision model with a third-party payer perspective to compare 3 strategies: (a) radical hysterectomy followed by tailored therapy; (b) primary chemoradiation; and (c) neoadjuvant chemotherapy followed by simple hysterectomy. The metric used for comparison was a cost-effectiveness ratio in dollars per patient cured. Cure was defined as survival disease-free at 5 years. An ICER was not reported. Radical hysterectomy was the least costly strategy per survivor at \$41,212. Chemoradiation and neoadjuvant chemotherapy was followed by simple hysterectomy cost \$43,197 and \$72,613 per survivor, respectively (128). The authors concluded that radical hysterectomy is the most cost-effective treatment for stage IB2 cervical cancer.

In a second analysis, Jewell et al. used a modified Markov state transition decision model to compare primary chemoradiation (CR) to primary radical hysterectomy with tailored adjuvant therapy (RH+TA) for the treatment of stage IB2 cervical cancer. A third-party (payer) perspective was assumed. A small percentage of patients in the RH+TA group were assumed to have the radical hysterectomy abandoned due to advanced disease not detected by preoperative positron emission tomography (PET)/computed tomography (CT). Patients undergoing completed radical hysterectomy were divided into 3 risk groups based on surgical pathologic risk features. On the basis of literature review, it was assumed that 5% of patients would have high-risk features on final pathology, 85% would have intermediate-risk features, and 10% low-risk features. Patients with high-risk features were assumed to receive adjuvant chemoradiation (4500 cGy external beam radiotherapy with weekly sensitizing cisplatin followed by vaginal cuff high-dose rate [HDR] brachytherapy). Patients with intermediate-risk features would either receive no adjuvant treatment or external beam radiotherapy plus chemotherapy. Patients at low risk for recurrence would receive no adjuvant treatment. Adverse events included in the model were: anemia, neutropenia, deep vein thrombosis/pulmonary embolism, gastrointestinal fistula, genitourinary fistula, hydronephrosis, bladder dysfunction, small bowel obstruction, radiation proctitis, cystitis, severe infection, and vaginal dysfunction. The costs for individual primary treatment modalities were obtained using 2007 national Medicare reimbursement and fee schedules (<http://www.cms.hhs.gov>). The costs associated with treatment of each severe (CTCAE grades 3–5) nonhematologic adverse event were obtained from the national database of the

AHRQ's HCUP (www.hcup.ahrq.gov). The model predicted 5-year overall survival of 79.6% in the RH+TA arm and 78.9% in the CR arm. The mean cost of RH+TA was \$27,840 compared to \$21,403 for CR. The ICER comparing RH+TA to CR was \$63,689 per additional YLS (129).

Although this analysis did not find that radical hysterectomy was cost-saving, sensitivity analysis showed that radical hysterectomy was potentially cost-effective (i.e., the cost per life-year saved was within the range considered acceptable—approximately \$50,000–75,000/life-year) (129). While Rocconi et al. found radical hysterectomy with tailored adjuvant therapy to be the least expensive option, Jewell et al. found that RH+TA was the costlier treatment option in the base case. The difference in the outcomes may be related to Jewell's assumption that a higher proportion of women with stage IB2 cervical cancer who are treated with RH will receive adjuvant radiotherapy (47% vs. 40%), or their lower cost estimates for radiation treatments, possibly due to the use of Medicare reimbursement data to approximate costs and an institutional practice of using LDR, which appears to be less costly than HDR.

The differences in the outcomes in these models demonstrate the difficulty in economic analyses and show how the assumptions, inputs, and design of a model are critical to its results. These models were strictly cost-effectiveness models and neither incorporated quality-of-life measures. Cost-effectiveness models that lack consideration of quality of life may under- or over-estimate the value of a given treatment strategy.

Quality-of-life-related preferences for treatment Jewell et al. elicited preferences for calculation of utility scores from cervical cancer survivors and the general public for the treatment of early-stage cervical cancer. The authors created descriptions of health states that included detailed information about available treatments for early-stage cervical cancer. Surgical scenarios ranged from minimally invasive radical hysterectomy with low-risk pathology requiring no additional treatment to aborted radical hysterectomy due to locally advanced disease followed by primary chemoradiation and brachytherapy. Primary chemoradiation (including teletherapy and brachytherapy) was also evaluated. Physical and emotional aspects of each treatment were outlined and, where appropriate, details about initial postoperative recovery, outpatient whole pelvic radiation, outpatient chemotherapy, and inpatient brachytherapy were described in each health state scenario. Common side effects were incorporated into each description. The TTO method was used. Health states describing chemoradiation were less preferred than health states describing surgery, regardless of whether adjuvant chemoradiation was given (Table 18.2). Even in health scenarios with similar 5-year survival, subjects ranked surgery followed by tailored adjuvant treatment as equivalent or slightly preferred over primary chemoradiation. The subject ranked a minimally invasive approach as most preferred, suggesting that an overnight hospitalization, smaller incision sites, and faster return to activities of daily living are preferred (130).

Use of radiation therapy in cervical cancer Intracavitary radiation treatment is recognized to play a significant and important role in the standard radical radiotherapy treatment of cervical carcinoma. The majority of centers worldwide use either low-dose rate (LDR) or high-dose rate (HDR) methods. Randomized trials have confirmed the apparent equivalence of HDR and LDR in terms of the incidence of adverse effects, tumor control, and survival (131). HDR is becoming more prevalent, possibly based on its outpatient nature, the ability to treat a greater number of patients, the ability to treat tumors at different sites, and the perceived cost savings to the health care system mainly due to the outpatient setting of the treatment. However, HDR treatment costs per insertion are frequently greater than

Table 18.2 Utility Scores Elicited from Members of the Public and Cervical Cancer Survivors for Health States Related to the Treatment of Newly Diagnosed Cervical Cancer

Rank	Treatment	Mean	95% Confidence Intervals
1	Minimally invasive radical hysterectomy No adjuvant treatment	0.94	0.89–0.99
2	Radical hysterectomy Low-risk features No adjuvant treatment	0.89	0.82–0.97
3	Radical hysterectomy Intermediate-risk features No adjuvant treatment	0.89	0.82–0.96
4	Radical hysterectomy Intermediate-risk features Adjuvant chemoradiation	0.80	0.72–0.89
5	Radical hysterectomy High-risk features Adjuvant chemoradiation High-dose rate brachytherapy	0.78	0.69–0.87
6	Primary chemoradiation	0.76	0.66–0.85
7	Aborted radical hysterectomy due to extent of disease Primary chemoradiation	0.68	0.57–0.79

LDR and increasing attention is now being paid to thorough health economic analysis by health care professionals in an attempt to reduce the escalating health care costs.

Jones et al. undertook a formal analysis of LDR versus HDR brachytherapy from a Canadian hospital perspective (132). The cost model incorporated fixed and direct costs arising from equipment purchases, equipment maintenance fees, costs of patient care, and operating costs (staff and operating room costs). The cost to a hospital of an HDR administration unit is greater than the costs of each type of LDR unit. On the basis of this cost difference and the practical limitations on the number of patients who can be accommodated by each machine per year, this study demonstrated that the LDR technique is less expensive when treating up to 80 patients per year. However, the ability to treat a significantly greater number of patients and the potential to treat other sites made the use of an HDR unit a more reasonable choice for centers where over 80 cervical cancer patients are treated annually. Therefore, purchase of an HDR unit is a cost-saving strategy for centers with a greater caseload.

Endometrial Cancer

Endometrial cancer is a disease in which outcomes research can be challenging; despite the high incidence of disease, the event

rate (recurrence or death) is low. The result of these characteristics is that any intervention must be extremely powerful to demonstrate a statistically significant improvement in cancer specific outcomes. As such, randomized clinical trials for cases that are at low- or intermediate-risk for recurrence may take a long time to accrue and demonstration of significance may be challenging. The CER approaches, therefore, may be quite relevant in endometrial cancer. CER in endometrial cancer spans the aspects of surgical management, the use of adjuvant radiation and chemotherapy, surveillance for disease recurrence, and the evaluation and management of individuals at risk for or diagnosed with Lynch syndrome-associated cancers.

Perioperative Setting

CER techniques have been most commonly utilized in the evaluation of surgical management of endometrial cancer, and most commonly are related to the cost-effectiveness of various interventions. Given the current controversies regarding the role and expense of preoperative testing, minimally invasive surgery, and the performance of a lymphadenectomy, significant opportunities exist to utilize CER to address these perioperative issues in endometrial cancer.

Preoperative Testing

The use of preoperative imaging in patients with clinical stage I endometrial cancer has, in certain circumstances, been demonstrated to identify disease that might not be amenable to resection. While certain authors supported the strategy of preoperative CT in patients planned to undergo surgery for endometrial cancer, others questioned the effectiveness and cost of this intervention. Bansal et al. performed a study evaluating patients with endometrial cancer who underwent a preoperative CT of the abdomen and pelvis (133). In 7/250 (3%) patients over a 16-year period, the CT results led to an alteration of the surgical plan. In patients with high-risk histology (serous, clear cell, and sarcoma), the plan was changed in up to 13% of cases. When the cost of imaging was incorporated into their model, the authors estimated that more than \$17,000 was expended to alter the management of 1 patient. As such, the authors argued that routine preoperative CT in patients with clinical stage I endometrial cancer was not cost-effective.

Surgical Approaches to Endometrial Cancer Staging

Laparotomy versus minimally invasive surgery. Over the last few decades, minimally invasive surgery has been incorporated into the management of many malignancies, including endometrial cancer. Initial reports of this surgical approach demonstrated the feasibility and acceptable toxicity of laparoscopic staging for endometrial cancer. Subsequently, randomized trials of laparotomy versus laparoscopy were reported, including studies from the Netherlands (134), Australia (135), and the U.S. (136), all demonstrating similar oncologic outcomes between groups. Furthermore, these trials demonstrated that laparoscopy was associated with a modest improvement in quality of life compared to laparotomy (137,138). Recently, the investigators from the Netherlands evaluated the cost of treatment relative to the survival and quality of life in subjects undergoing laparotomy or laparoscopic staging of their endometrial cancer (139). These investigators suggested that despite a slightly increased cost for minimally invasive surgery (higher operative costs but lower hospital stay costs), total laparoscopic hysterectomy remains cost-effective because of the low rate of complications seen in the minimally invasive arm compared with laparotomy. While the absolute costs seen in this population may not be identical to that in other geographic regions, it is likely that trends favoring the cost-effectiveness of minimally invasive surgical staging for endometrial cancer would be similar to those in other parts

of the world. This group also performed a meta-analysis of 12 trials of laparoscopic endometrial cancer surgery and reached the conclusion that laparoscopy was cost-effective compared to laparotomy (10), acknowledging that the lack of quality-of-life data precluded a definitive statement regarding the utility of this procedure from a societal perspective.

Laparoscopy versus robotic surgery. In 2006, the FDA cleared the first computer-aided (robotic) surgical system for hysterectomy. There has subsequently been a rapid incorporation of robotic surgery into gynecologic cancer practices, mainly for the treatment of endometrial cancer. Initial reports of this surgical approach demonstrated feasibility and acceptable toxicity. However, the initial purchase price of the robot (>\$1 million), yearly maintenance contract (>\$100,000 annually), and limited use disposable instruments add a fixed cost to this procedure over laparoscopy or laparotomy. Given the expense of robotic surgery, analyses of the cost of robotic surgery have been published, often with differing conclusions. Initially, Bell et al. described a series of patients who underwent abdominal, laparoscopic, or robotic staging for endometrial cancer, with the robotic approach being found less costly compared with laparotomy, but not significantly more expensive than laparoscopy (9). Subsequent to this report, other CER approaches have been utilized to assess the cost-effectiveness and comparative effectiveness of robotic surgery compared to other surgical approaches. Barnett et al. utilized decision modeling from the perspectives of both society and the hospital (with and without the cost of the purchase of the robot incorporated) to assess the impact of surgical approach (laparotomy, laparoscopy, and robotic) for staging of endometrial cancer (7). These authors concluded that while laparoscopy is the least expensive approach, the decreased societal cost associated with an early return to normal function makes robotic surgery less expensive than laparotomy. In sensitivity analysis, when the costs of disposable instruments and equipment are minimized to less than one-half their current cost, robotic surgery becomes the least costly approach. The modeling approach with sensitivity analyses is critically important in helping to understand the factors which drive cost in endometrial cancer surgery, and to acknowledge that the perspective from which the analysis is taken significantly impacts the conclusions that can be drawn. Additionally, a population-based CER analysis was undertaken by Wright et al. describing more than 2,400 women who underwent minimally invasive surgery for endometrial cancer, 58% robotically and 42% laparoscopically (140). These authors found similar rates of complications and an increased cost with robotic surgery, and concluded that longer term outcome data regarding robotic surgery are necessary before this approach is considered standard for the management of endometrial cancer. Collectively, the CER data regarding robotic endometrial cancer surgery suggest an increased cost, decreased morbidity compared with laparotomy, and cost-effectiveness that varies based on the perspective from which the data are interpreted.

Lymphadenectomy for surgical staging. Following two randomized trials suggesting that lymphadenectomy for endometrial cancer does not improve outcomes (141,142), the role of this procedure in the routine management of endometrial cancer has undergone increased scrutiny. Various strategies have been suggested to identify patients who are at highest risk for metastasis to the lymph nodes, and generally incorporate tumor grade, depth of myometrial invasion, histology and tumor size. Various authors have evaluated the cost-effectiveness of the strategies of routine lymphadenectomy versus a selective staging strategy. Kwon et al. suggested that as tumor grade increases, lymphadenectomy is more cost-effective than its omission, mainly due to the reduced rate of radiation in node-negative patients (143). Cohn et al. modeled grade 1 cancers and demonstrated that even in this group of patients at low risk for

lymph node metastasis, routine lymphadenectomy was more cost-effective than a strategy wherein lymphadenectomy is performed selectively, assuming a lower rate of adjuvant radiation in the staged patients (144). Importantly, these authors did not include an analysis of complications or quality of life in their models. Another approach to address the role of surgical staging would be to develop a test that could predict, prior to surgery, which patients are at highest risk for the presence of lymph node metastasis. Havrilesky et al. modeled such a hypothetical test and determined that a test that could reliably predict lymph node metastasis could be cost-effective as long as it was fairly inexpensive (145). Importantly, the cost-effectiveness of such a strategy is independent of the cost of adjuvant therapy in their model.

Adjuvant radiation therapy. A number of studies have been performed analyzing the comparative cost and cost-effectiveness of adjuvant radiation in patients with endometrial cancer. Lachance et al. reported a model that included patients with stage I endometrial cancer, and evaluated strategies of observation, vaginal brachytherapy, and pelvic teletherapy (146). The authors estimated that vaginal brachytherapy would significantly reduce recurrences at an expense of almost \$66,000 per survivor. While teletherapy could reduce recurrences as well, its use was associated with greater expense without an increase in survival beyond that of vaginal brachytherapy. In another study in patients with early-stage disease at intermediate risk for recurrence, Rankins et al. created a decision model demonstrating that the cost-effectiveness of adjuvant pelvic teletherapy was dependent on the risk of recurrence and the efficacy of adjuvant therapy; in the population enriched for a high risk for recurrence, radiation was cost-effective (147). These data suggest that routine adjuvant radiation for early-stage endometrial cancer is not cost-effective. However, in patients at a high risk for recurrence, this balance shifts, with adjuvant therapy becoming adequately cost-effective to recommend its use. Again, these studies are plagued by their lack of information on quality of life, specifically given the increasing data suggesting a deterioration of the quality of life domains of sexuality, urinary, and intestinal functions in patients receiving certain forms of radiation for endometrial cancer (148).

Surveillance for endometrial cancer recurrence. Given that the survival of women with endometrial cancer is approximately 85% overall, investigators have challenged the notion that routine intermittent surveillance for pelvic examination and vaginal cytology (with or without chest imaging) is cost-effective or even necessary for most women with endometrial cancer. In support of the trend toward decreased intensity of surveillance, it has been estimated that the cost of routine vaginal cytology to identify a single asymptomatic recurrence is more than \$44,000 (149). Whether the identification of this asymptomatic individual leads to improved outcomes is even less certain (150).

Lynch syndrome. From clinic-based studies, it is estimated that 2.3% of patients with endometrial cancer have Lynch syndrome as the cause of their disease (151). Given the relatively low prevalence of the disease, the ability to distinguish these patients from all those with sporadic disease would be enormously beneficial, as the probands and their families could be introduced to prevention and screening interventions that might decrease the risk of dying from Lynch-related malignancies. However, the clinical Amsterdam criteria are relatively insensitive and non-specific in identifying Lynch syndrome. Thus, many institutions

have begun utilizing immunohistochemistry (IHC) for the DNA mismatch repair genes as an initial screen for Lynch syndrome. Health economic studies of this strategy have demonstrated that utilizing IHC in patients with a first-degree relative with a Lynch-associated cancer is cost-effective (152). Other investigators, while acknowledging that clinical judgment is key to the interpretation of their model, have shown that the routine use of IHC, with a subsequent triage to genetic testing if IHC is abnormal, is potentially cost-effective when compared to other screening strategies (153).

Additionally, the cost-effectiveness of strategies to prevent the disease in probands with known Lynch syndrome has been evaluated. Kwon et al. demonstrated that in this population, annual surveillance with endometrial biopsy, pelvic ultrasound, and CA-125 at 30 years plus risk-reducing hysterectomy and oophorectomy at 40 years is the most effective strategy, though substantially more expensive than preventative surgery alone or screening alone, with an additional \$194,000 spent per increase in year of survival compared to the next best strategy (93). The cost-effectiveness of risk-reducing surgery has also been confirmed by Yang et al., who demonstrated that this intervention is more cost-effective than either yearly examination or yearly invasive screening for malignancy (154).

Summary

Gynecologic oncology provides a rich opportunity to investigate the comparative effectiveness of various diagnostic, therapeutic, screening, and preventative strategies. While the field is still relatively young, substantial knowledge about these strategies has been gained through CER techniques and modeling. Continued investigation with refinement of CER tools for the investigation of gynecologic cancer is needed to advance the state of knowledge.

KEY POINTS

1. Comparative effectiveness research (CER) provides the framework for studies that compare the potential harms and benefits of strategies to prevent, diagnose, or treat gynecologic malignancy.
2. Health economic studies, including cost-effectiveness and cost-utility analyses, are a subset of CER in which medical interventions are compared on the basis of their relative costs, as well as their potential harms and benefits.
3. A key factor in the development of a cost-utility model is the incorporation of quality of life, which requires a preference-based utility. The utility may be derived using a variety of quality-of-life-related instruments. Use of the utility allows the results of a model to be expressed in QALYs, which is a standard effectiveness outcome.
4. The results of health economic decision models are highly dependent on their perspective and the assumptions made in their construction.
5. Uncertainty in health economic models is best described using multiple sensitivity analyses.
6. There is a growing body of CER evidence to guide clinical and resource allocation decisions in gynecologic oncology.

Vulva

JOHN W. MORONEY ■ CHARLES KUNOS ■ EDWARD J. WILKINSON
■ CHARLES F. LEVENBACK

INTRODUCTION

Malignant tumors of the vulva are rare and account for less than 5% of all cancers of the female genital tract. In 2012, there will be an estimated 4,490 new cases of, and 950 deaths from, invasive vulvar carcinoma in the United States (1). Because of its low incidence, most primary care providers will never encounter a patient with vulvar cancer. Although a rare patient with vulvar cancer will present without symptoms, the vast majority of women with vulvar cancer initially present with complaints such as vulvar irritation, pruritis, pain, or a mass that does not resolve. The interval between the onset of symptoms and the diagnosis of cancer can be protracted when a woman who is embarrassed by new vulvar symptoms delays seeking care, or a physician prescribes empiric topical therapies without a proper physical examination or tissue biopsy confirmation. Jones and Joura evaluated the clinical events preceding the diagnosis of squamous cell carcinoma of the vulva and found that 88% of patients had experienced symptoms for more than 6 months, 31% of women had 3 or more medical consultations prior to the diagnosis of vulvar carcinoma, and 27% had applied topical estrogen or corticosteroids to the vulva (2).

The vulva is covered by keratinized squamous epithelium; accordingly, the majority of malignant vulvar tumors are squamous cell carcinomas. Consequently, our current understanding of the epidemiology, spread patterns, prognostic factors, and survival data for vulvar cancer is largely derived from experience with squamous cell carcinomas. Malignant melanoma is the second most common cancer of the vulva. Although there is some consensus regarding the behavior and treatment of vulvar melanoma, its rarity has thus far precluded the conduct of robust, prospective clinical trials. A number of other malignant tumors, both epithelial and stromal in origin, arise from normal vulvar tissue and are discussed in detail later in this chapter. Finally, the vulva may be secondarily involved with malignant disease originating in the cervix, bladder, anorectum, colon, breast, or other organs.

The traditional therapeutic approach to vulvar cancer has been radical surgical excision of the primary tumor and

inguinofemoral lymphadenectomy. Experience has shown that survival is improved with the administration of postoperative radiation therapy to selected patients deemed to be at high risk for locoregional failure. More recently, the use of neo-adjuvant radiotherapy with concomitant radio-sensitizing chemotherapy has proven to be effective in treating vulvar cancer patients for whom radical surgery would be either too morbid or technically not feasible. New surgical techniques, including sentinel lymph node biopsy, hold the promise of better outcomes for patients with early disease. An individualized approach to vulvar cancer management, often employing multiple modalities in an effort to achieve disease control with better cosmetic results and sexual function, is now the norm. These and other topics pertinent to the principles of management of women with vulvar cancer are the subjects of this chapter.

ANATOMY

The vulva consists of the external genital organs—including the mons pubis, labia minora and majora, clitoris, vaginal vestibule, and perineal body—and their supporting subcutaneous tissues. The vulva is bordered superiorly by the anterior abdominal wall, laterally by the labiocrural fold at the medial thigh, and inferiorly by the anus. The vagina and urethra open onto the vulva. The mons pubis is a prominent mound of hair-bearing skin and subcutaneous adipose and connective tissue that is located anterior to the pubic symphysis. The labia majora are two elongated skin folds that course posterior from the mons pubis and blend into the perineal body. The labia minora are a smaller pair of skin folds medial and parallel to the labia majora that extend inferiorly to form the margin of the vaginal vestibule. Superiorly, the labia minora separate into 2 components that course above and below the clitoris, fusing with those of the opposite side to form the prepuce and frenulum, respectively. The skin of the labia minora contains sebaceous glands near its junction with the labia majora, but it is not hair-bearing and it has little or no underlying adipose tissue. The clitoris is supported externally

David H. Moore, Wui-Jin Koh, and William P. McGuire contributed to prior editions of this chapter

by the fusion of the labia minora (prepuce and frenulum) and is approximately 2 to 3 cm anterior to the urethral meatus. It is composed of erectile tissue organized into the glans, body, and two crura. Two loosely fused corpora cavernosa form the body of the clitoris and extend superiorly from the glans, ultimately dividing into the two crura. The crura course laterally beneath the ischiocavernosus muscles and attach to the ischial rami.

The vaginal vestibule is situated in the center of the vulva and is homologous to the male distal urethra. It has squamous mucosal epithelium that is demarcated bilaterally and posteriorly by the junction with the keratinized epithelium at Hart's line, located on the medial labia minora and inferiorly on the perineal body. The vagina, urethra, periurethral glands, minor vestibular glands, and the Bartholin's glands open onto the vestibule. Anteriorly, the minor small vestibular glands are located beneath the vestibular mucosa and open onto its surface predominantly on the more anterior vestibule. The vestibular bulbs, a loose collection of bilateral erectile tissue covered superficially by the bulbocavernosus muscle, are located laterally. The Bartholin's glands, two small, mucus-secreting glands situated within the subcutaneous tissue of the posterior labia majora, have ducts opening onto the posterolateral portion of the vestibule. The perineal body is a 3 to 4 cm band of skin and subcutaneous tissue located between the posterior extensions of the labia majora. It separates the vaginal vestibule from the anus and forms the posterior margin of the vulva.

Vascular Anatomy and Neurologic Innervation

The vulva has a rich blood supply derived primarily from the internal pudendal artery, which arises from the anterior division of the internal iliac (hypogastric) artery, and the superficial and deep external pudendal arteries, which arise from the femoral artery. The internal pudendal artery exits the pelvis and passes behind the ischial spine to reach the posterolateral vulva, where it divides into several small branches to the ischiocavernosus and bulbocavernosus muscles, the perineal artery, artery of the bulb, urethral artery, and dorsal and deep arteries of the clitoris. Both external pudendal arteries travel medially to supply the labia majora and their deep structures. These vessels anastomose freely with branches from the internal pudendal artery. Innervation of the vulva is derived from multiple sources and spinal cord levels. The mons pubis and upper labia majora are innervated by the ilioinguinal nerve (L1) and the genital branch of the genitofemoral nerve (L1–2). Either of these nerves may be easily injured during pelvic lymph node dissection, with resulting paresthesias. The pudendal nerve (S2–4) enters the vulva in parallel with the internal pudendal artery and gives rise to several branches that innervate the lower vagina, labia, clitoris, perineal body, and their supporting structures.

Groin Anatomy and Lymphatic Drainage

Vulvar lymphatics run anteriorly through the labia majora, turn laterally at the mons pubis, and drain primarily into the superficial inguinal lymph nodes. Dye studies by Parry-Jones demonstrated that vulvar lymphatic channels do not extend laterally to the labiocrural folds and do not cross the midline, unless the site of dye injection is at the clitoris or perineal body (3).

The vulvar lymphatics drain to the superficial inguinal lymph nodes located within the femoral triangle formed by the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially. There are 8 to 10 inguinal lymph nodes lying along the saphenous vein and its branches between Camper's fascia and fascia overlying the femoral vessels (Fig. 19.1A–C) (4). The first draining lymph node is termed the sentinel lymph node (SLN) and can

be identified only by the use of various lymphatic mapping techniques. The SLN is frequently found medial to the femoral vein just above the adductor muscle. Second echelon lymph nodes may be in the groin or pelvis. Cloquet's node, or the most superior inguinal lymph node, is located under the inguinal ligament. Lymphatic drainage from the SLN is sequentially to the external iliac, common iliac, and aortic lymph nodes (Fig. 19.1A–C).

The fossa ovalis is a crescent-shaped terminus of the fascia lata and the site where vascular and lymphatic structures meet with the femoral vessels. The cribriform fascia is a term widely used in the literature describing the anatomy of the groin and is said to cover the fossa ovalis. The cribriform fascia is hard to identify and is more of a "lamina" than an actual fascia. SLN biopsy with lymphatic mapping deemphasizes the need to identify the cribriform structure and focuses the surgeon's attention on functional *in vivo* surgical anatomy rather than textbook descriptions of lymph node locations.

EPIDEMIOLOGY

An estimated 4,490 women were diagnosed with vulvar cancer in the United States in 2012, and approximately 950 will die of the disease (1). Vulvar squamous cell carcinoma accounts for approximately 3% to 5% of all gynecologic malignancies and 1% of all carcinomas in women, with an incidence rate of 1 to 2 per 100,000 women (1). Most vulvar cancers occur in postmenopausal women in the seventh decade, although more recent reports have identified a trend toward younger age at diagnosis (5,6). Earlier observational studies suggested associations between hypertension, diabetes mellitus, and obesity and vulvar carcinoma; however, subsequent analyses have not confirmed the prognostic significance of these diagnoses (7).

Several infectious agents have been proposed as possible etiologic agents in vulvar carcinoma, including granulomatous infections, herpes simplex virus, and, most notably, human papillomavirus (HPV). HPV infection is present in virtually 100% of women with cervical cancer. The relationship between HPV infection and vulvar cancer is much less straightforward. This is likely due to the different etiologic pathways that are believed to be responsible for vulvar cancer. These different etiologic pathways are discussed in detail in the chapter on preinvasive disease; however, because of subject matter overlap, some of the data related to HPV and invasive squamous cell carcinoma of the vulva are discussed here.

Vulvar condylomas have a well-described relationship to HPV, and strong associations between vulvar condylomas and the later development of vulvar cancer have been identified (8). The role of HPV in the development of premalignant and malignant lesions of the vulva has become clearer as molecular techniques for HPV detection and mutational analyses have improved (9). Earlier studies identified HPV DNA in both invasive and carcinoma *in situ* lesions via immunohistochemistry. More recent studies have used DNA detection methods such as polymerase chain reaction (PCR) and *in situ* hybridization to detect high-risk serotypes (9). Among HPV serotypes, 16 is the most common; however, many other serotypes, including 18, 31, 33, and others, have been implicated (9). HPV DNA can be identified in approximately 85% of intraepithelial lesions (range, 42% to 100%), but is seen in only 10% to 50% of invasive lesions (9). The reason such a wide range of associated HPV is seen associated with vulvar intraepithelial neoplasia (VIN) and vulvar cancer has to do with differences between studies regarding which VIN subtypes (usual or differentiated) are being studied, different DNA detection methods with different sensitivity, and differences between studies regarding which HPV serotypes are being assayed.

Although HPV DNA is associated with the vast majority of intraepithelial lesions (~85%), it is much less commonly seen in association with invasive lesions (~40%) (9). Marked differences

FIGURE 19.1. These historic figures illustrate some of the problems depicting the lymphatic anatomy of the groin. **A** and **B** illustrate vessels, muscles, and nerves accurately. **A** refers to sentinel nodes; however, this is based on location rather than a mapping procedure, which is misleading. **B** shows nodes between the femoral artery and vein. Lymph nodes between the vessels are common in the pelvis but not in the groin. **C**: shows direct drainage from the clitoral area of the vulva to pelvic lymph nodes. This drainage pattern is not observed with preoperative or intraoperative lymphatic mapping studies.

between HPV positivity in VIN and vulvar cancers are also seen with respect to age. Basta et al. conducted a retrospective case control study examining the coexistence of HPV and the incidence of both VIN and stage I vulvar cancer. HPV infection was present in 61.5% of cases of VIN and vulvar cancer in women aged less than or equal to 45 years, and in 17.5% of women older than 45 years (10).

Chronic immunosuppression and tobacco smoking have also been linked as cofactors for the development of invasive vulvar cancer (11,12). Vulvar cancer incidence is increased in female renal transplant patients as well as women with HIV and AIDS

(11,13). Smoking is an independent risk factor for the development of squamous cell carcinoma of the vulva, although the reason for this is unclear. One hypothesis is that genetic variations in T-cell-mediated IL-2 responses among smokers may explain differential susceptibility to the development of squamous vulvar carcinomas (12). Significant correlations between smoking status, historical number of sexual partners, history of genital warts, and a history of an abnormal Pap smear have been detailed by Brinton et al. (Table 19.1) (7).

Chronic vulvar inflammatory lesions, such as vulvar dys- trophies, including lichen sclerosus (LS), lichen planus, lichen

simplex chronicus, squamous cell hyperplasia, and vulvar intraepithelial neoplasia II/III (usual as well as differentiated types), particularly differentiated VIN (dVIN), have been suggested as precursors of invasive squamous cancers (14,15). Carli et al. suggested a possible role of LS as a precursor to vulvar cancer based on their observation that 32% of vulvar cancer cases not related to HPV were associated with LS (16). More recently, in a pathologic reevaluation of patients with a diagnosis of LS who were followed clinically for a minimum of 10 years, van de Nieuwenhof and colleagues identified concordant diagnoses of LS in 58/61 patients who did not progress to cancer, and concordant diagnoses of LS in only 29/60 patients who were identified with a subsequent diagnosis of vulvar cancer. The majority of patients reclassified as having something other than LS were considered to have dVIN (25/31 patients). This study highlights dVIN as a uniquely at-risk histology that deserves prompt treatment and close follow-up. Differentiated vulvar intraepithelial neoplasia is often found in lesions, previously diagnosed as LS, that have progressed to vulvar squamous cell carcinoma (15).

In an observational study of women with carcinoma *in situ*, 7 of 8 untreated cases progressed to invasive carcinoma within 8 years, and 4 of 105 treated women presented with invasive tumors from 7 to 18 years later (17). In a subsequent study of 405 cases of VIN 2 to 3, Jones et al. found that 3.8% of patients had developed invasive cancer despite therapy, and 10 untreated patients had developed invasive cancer in 1.1 to 7.3 years (mean, 3.9 years) (18). Although some intraepithelial lesions regress spontaneously, it appears that a significant number persist or progress to invasive cancer.

Trimble et al. postulated that squamous carcinoma of the vulva may represent a final common endpoint of heterogeneous

etiologic pathways (19). According to their studies, two histologic subtypes, those with basaloid or warty features, are associated with HPV, whereas keratinizing squamous carcinomas are not. Furthermore, basaloid or warty carcinomas are associated with classic risk factors for cervical carcinoma, including age at first intercourse, lifetime number of sexual partners, prior abnormal Pap smears, smoking, and lower socioeconomic status. Keratinizing squamous carcinomas are weakly linked to these factors, and in some cases not at all.

Mitchell et al. evaluated 169 women with invasive vulvar cancers and noted that second genital squamous neoplasms occurred in 13% of cases (20). The risk of a second primary tumor was significantly increased in cancer cases with HPV DNA, intraepithelioid growth pattern, or adjacent dysplasia. These observations support the concept that some squamous lesions may be initiated by sexually transmitted viruses capable of producing neoplastic change within the entire field of the lower genital tract. The obvious clinical implication of this observation is that a patient with an established squamous lesion of the vulva, vagina, or cervix needs to be evaluated and monitored for new or coexistent lesions at other sites.

NATURAL HISTORY (PATTERNS OF SPREAD)

Vulvar cancers metastasize in 3 ways: (a) local growth and extension into adjacent organs, (b) lymphatic embolization to regional lymph nodes in the groin, and (c) hematogenous dissemination to distant sites.

Inguinal node metastasis can be predicted by the presence of multiple risk factors, including tumor diameter, higher histologic grade (degree of differentiation), depth of stromal invasion, and lymphovascular space invasion (21,22). Clinically important observations regarding nodal metastases include the following: (a) inguinal nodes are the most frequent site of lymphatic metastasis; (b) in-transit metastases within vulvar epithelium and deep tissues are exceedingly rare, suggesting that most initial lymphatic metastases represent embolic phenomena; (c) Metastasis to the contralateral groin or deep pelvic nodes are unusual in the absence of ipsilateral groin metastases; and (d) nodal involvement generally proceeds in a stepwise fashion from the superficial inguinal to the deep inguinal and then to the pelvic nodes (21,22).

Spread beyond the inguinal lymph nodes is considered distant metastasis (stage IVB). Such metastases occur either due to sequential lymphatic spread to secondary and tertiary nodal groups or as a result of hematogenous dissemination to more distant sites, such as bone, lung, or liver. Distant metastases are uncommon at initial presentation and are usually seen in the setting of recurrent disease.

CLINICAL PRESENTATION

Most women with vulvar cancer present with pruritus and a recognizable lesion. Selecting the most appropriate site for biopsy in women with condyloma, chronic vulvar LS, multifocal high-grade squamous intraepithelial lesions (VIN 3), or Paget's disease can be difficult, and multiple biopsies may be required. Optimal management for any patient presenting with a suspicious lesion is to proceed directly to biopsy under local analgesia. Tissue biopsies should include the cutaneous lesion in question and representative contiguous underlying stroma, so that the presence and depth of invasion (DOI) can be accurately assessed. Because DOI is a central issue in the management of vulvar cancer, punch biopsies are encouraged and shave biopsies are discouraged in the diagnosis of vulvar lesions. If invasion is suspected and a punch biopsy fails to confirm the clinical suspicion, then an incisional or excisional biopsy should be performed. Primary care physicians should be encouraged not to excise a lesion if avoidable, to facilitate the sentinel node procedure by a gynecologic oncologist. Figure 19.2 illustrates a relatively early-stage vulvar cancer.

DIAGNOSTIC EVALUATION

The evaluation of a patient with vulvar cancer must take into consideration the clinical extent of disease and the presence of

FIGURE 19.2. Early-stage vulvar cancer.

coexisting medical illnesses. Initial evaluation should include a detailed physical examination with measurements of the primary tumor, assessment for extension to adjacent mucosal or bony structures, and clinical evaluation of the inguinal lymph nodes. It is helpful to record the distance from vital structures such as the clitoris, urethral meatus, and anus, since these structures are a limiting factor for obtaining adequate surgical margins. Diagnostic imaging is not required in women with small primary lesions and normal body habitus. In obese women, the inguinal nodes are difficult to palpate and imaging may be helpful in identifying the presence of lymphadenopathy. Patients with large or fixed tumors, and those who are difficult to examine in the clinic, may benefit from an exam under anesthesia with cystourethroscopy and proctosigmoidoscopy. Figure 19.3 illustrates an advanced tumor, for which such an approach can help determine resectability.

Radiographic studies that have been described as beneficial are computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), ultrasound, and single photon emission CT (SPECT) (23–26). While newer imaging modalities can be of benefit in treatment planning, it is also important to note that published series are small, and no individual modality has been shown to be superior to others in terms of detecting metastatic or recurrent disease. The best modality might differ depending on the practice situation and skills of the diagnostic imaging consultants. Suspicious lymph nodes should be biopsied if the findings would alter the surgical plan. Because neoplasia of the female genital tract is often multifocal, evaluation of the vagina and cervix, including cervical cytologic screening, should always be performed in women with vulvar

FIGURE 19.3. Advanced vulvar cancer.

neoplasms (27). Lymphoscintigraphy will be discussed later in this chapter.

STAGING

The International Federation of Gynecology and Obstetrics (FIGO) adopted a modified surgical staging system for vulvar cancer in 1989. This staging system was revised in 1995 and

more recently in 2009 (Table 19.2) (28,29). The 2009 revision was performed to address issues with the 1995 version, namely, the lack of a useful prognostic spread among stages, as well as significant prognostic heterogeneity among stage III patients. Since the 1995 revision, much has been learned about the significance of the number of involved nodes, the size of inguinal metastases, and nodal morphology.

The technique recommended by the International Society for the Study of Vulvar Disease, the International Society of Gynecologic Pathologists, the College of American Pathologists, and

Table 19.2 Integrated 2009 FIGO and AJCC Staging System for Squamous Cell Carcinoma of the Vulva

FIGO		AJCC		
		T	N	M
		Tis: No invasion past basement membrane (not in FIGO system)		
I: Tumor confined to the vulva				
1A	Lesions ≤ 2 cm in size, confined to vulva or perineum and with stromal invasion ≤ 1.0 mm, no nodal metastasis	T1a	N0	M0
1B	Lesions > 2 cm in size or with stromal invasion > 1.0 mm, confined to the vulva or perineum, with negative nodes	T1b	N0	M0
II	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus), with negative nodes	T2	N0	M0
III	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus), with positive inguinofemoral lymph nodes	T1 or T2	N1-N3	M0
IIIA	(i) 1–2 lymph node metastasis(es) (< 5 mm), or (ii) 1 lymph node metastasis (≥ 5 mm)	T1 or T2	N1a = (i) N1b = (ii)	M0
IIIB	(i) 3 or more lymph node metastases (< 5 mm) or (ii) 2 or more lymph node metastases (≥ 5 mm)	T1 or T2	N2a = (i) N2b = (ii)	M0
IIIC	Positive nodes with extracapsular spread	T1 or T2	N2c N3 = inguinal skin ulceration or fixed nodes	M0
IV	Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures	T3 = any size, involves upper urethra, bladder, rectum, bone		
IVA	Tumor invades: (i) upper urethral and / or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) fixed or ulcerated inguinofemoral lymph nodes	T3		M0
IVB	Distant metastasis: includes pelvic nodes	T1, T2 or T3		M1
		AJCC stage groupings		
		Stage	T, N, M combination

		IIIC	T1 or T2, N2c, M0	
		IVA	Either T1 or T2, N3, M0 or T2, any N, M0	
		IVB	any T, any N, M1	

FIGURE 19.4. Methods for measurement for vulvar superficially invasive carcinomas. Depth of invasion (**A**): the measurement from the epithelial stromal junction of the most superficial dermal papillae to the deepest point of invasion. This measurement is defined as the depth of invasion and is used to define stage IA vulvar carcinoma. The measurement (**B**) is the thickness of the tumor: from the surface of the lesion to the deepest point of invasion. Measurement (**C**) is from the bottom of the granular layer to the deepest point of invasion. This is also defined as thickness of the tumor in cases where there is a keratinized surface. The International Society of Gynecological Pathologists and the World Health Organization recommend that both the depth of invasion and the thickness of tumor, as well as the method of measurement, be defined in the pathology reports.

the World Health Organization to assess depth of stromal invasion is to measure from the base of the epithelium (epithelial-stromal junction) at the nearest superficial dermal papillae to the deepest point of tumor penetration (30). These definitions and methods of measurement are supported by the recent CAP-ASCCP LAST terminology project (Fig. 19.4) (31).

Among squamous cell carcinomas limited to the vulva, those with a DOI less than or equal to 1 mm are associated with a <1% risk for lymph node metastasis. Tumors with a DOI of 1.1 to 3.0 mm are associated with lymph node metastases in 6% to 12% of patients, and approximately 15% to 20% of tumors with a DOI of 3.1 to 5.0 mm are associated with positive lymph nodes (32).

In the 2009 revision, all stage I and stage II patients have uninvolved lymph nodes. There is no clear definition of how many lymph nodes constitutes an adequate evaluation. SLN biopsy is not mentioned as a requirement; however, the emphasis on the size of micrometastases in stage III implies that an SLN biopsy is performed either alone or as part of a lymphadenectomy.

The new staging system adds 3 pathologic groupings within stage III (a, b, and c), each of which contains prognostic significance. These 3 groups are number of positive nodes, size of the largest inguinal node metastasis, and the presence or absence of extracapsular extension. These pathologic features have been shown in multiple studies to be the strongest predictors of mortality related to vulvar cancer (28).

The other notable difference in the new schema is the absence of stage difference based on unilaterality versus bilaterality of groin involvement; any groin metastasis is considered stage III

disease. As in 1995, the 2009 FIGO staging guidelines for vulvar cancer were devised with correlation for the American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) classification scheme (Table 19.2) (33). Tumor assessment is based on physical examination, with endoscopy in cases of bulky disease. Nodal status is determined by the surgical evaluation of the groins. The presence or absence of distant metastases should be based on an individualized diagnostic workup based on the patient's clinical presentation (28).

Because of the infrequent incidence of vulvar melanoma there has historically been a paucity of data to guide staging algorithms for patients with this disease. Recent data though support an assertion that AJCC staging guidelines (updated in 2010) for cutaneous melanoma should be applied to vulvar melanoma. Moxley et al. (34) examined 77 cases of vulvar melanoma from 5 academic medical centers, applying the 2002 modifications of the AJCC staging system for cutaneous melanoma, Breslow thickness and Clark level to all patients. Breslow's thickness was associated with recurrence ($p = 0.002$) but not survival; however, the AJCC-2002 staging system was predictive of overall survival ($p = 0.006$) in patients with vulvar melanoma (34). It is important to emphasize that primary tumor thickness (using Breslow's method) and nodal status are the primary determinants of survival in this disease. Also important, however, are the presence or absence of ulceration and mitotic rate; these descriptors also factor prominently in the staging of cutaneous melanoma (Table 19.3).

PATHOLOGY

Most vulvar malignancies arise within squamous epithelium. Although the vulva does not have an identifiable transformation zone, as the cervix does, squamous neoplasms arise most commonly on the labia minora, clitoris, posterior fourchette, perineal body, or medial aspects of the labia majora. Within the vulvar vestibule and fourchette, squamous neoplasia may arise where keratinized stratified squamous epithelium transitions to the nonkeratinized squamous mucosa of the vestibule, also known as Hart's line (35).

Most vulvar squamous carcinomas arise within areas of epithelium associated with a recognizable epithelial cell abnormality. Approximately 60% of cases have adjacent HSIL (VIN 3). In cases of superficially invasive squamous carcinoma of the vulva, the frequency of adjacent HSIL (VIN 3) approaches 85% (36). Lichen sclerosis, usually with associated hyperplastic features, and/or HSIL (VIN 3), can be found adjacent to vulvar squamous cell carcinoma in 15% to 40% of the cases (37,38). Granulomatous disease is also associated with vulvar squamous cell carcinoma; however, this is not a commonly associated finding in the United States. Thus, vulvar squamous cell carcinoma precursors can be considered in distinct groups: those associated with HPV, "usual" VIN, and those that are not (e.g., those associated with LS, chronic granulomatous disease) (see Epidemiology section).

Epithelial Carcinomas

Squamous Cell Carcinomas

The term microinvasive carcinoma is not recognized as meaningful in reference to vulvar cancer because there are no commonly agreed on pathologic criteria established for this term. The recent CAP-ASCCP terminology committee on Lower Anogenital tract terminology (the LAST committee) stated that the descriptor "superficially invasive squamous cell carcinoma" be defined as stage IA carcinoma, and that the term "microinvasive

Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

carcinoma” not be used in reference to vulvar squamous cell carcinoma (31). The DOI is defined as the measurement from the epithelial dermal junction of the most superficial adjacent dermal papillae to the deepest point of invasion (31). In comparison, tumor thickness is measured from the overlying surface epithelium or from the bottom of the granular layer if the surface is keratinized, to the deepest point of invasion, as specified by the International Society of Gynecologic Pathologists (ISGYP), the World Health Organization, and FIGO (Fig. 19.4).

Stage I squamous carcinomas of the vulva with a DOI of 3 mm have a lymph node metastasis rate averaging 12%. Tumors with a DOI of 5 mm or more have a lymph node metastasis rate of at least 15%. Tumors with a DOI of 1 mm or less carry little risk of lymph node metastasis (30).

DOI and tumor thickness are separately defined and measured because considerable variations can exist among measurements from various superficial points in tumors of approximately 1 mm (Fig. 19.4) (39). There are significant differences between tumor DOI and thickness when superficially invasive tumors are measured. Tumors with invasion deeper than 1 mm can be readily measured by determining thickness, but tumors with surface ulceration may have a thickness, as measured from the surface, significantly less than the DOI. With large tumors, thickness may be the only reliable measurement because of the lack of identifiable adjacent dermal papillae.

In addition to tumor stage and depth or thickness, other pathologic features include vascular space invasion, growth pattern of the tumor, grade of the tumor, and tumor type. Vascular space involvement can be defined as tumor within an endothelial lined vascular space. Strict pathologic criteria require that the tumor be attached to the wall of the vessel, but this is not observed in all cases. Vascular space involvement by squamous cell carcinoma of the vulva is associated with a higher frequency of lymph node metastasis and a lower overall 5-year survival rate. No reliable methods unambiguously predict lymph node metastasis by quantitation of vascular space involvement by tumor.

Tumor growth pattern influences the rate of lymph node metastasis and survival in tumors exceeding 1 mm in DOI. In stage IA vulvar carcinomas, tumor growth pattern does not influence the risk of node involvement (32). Three factors describe tumor growth patterns: confluent; compact (pushing pattern); and finger-like (or spray or diffuse), a pattern also described as poorly differentiated (32). Confluent growth is defined as a tumor mass composed of interconnected tumor exceeding 1 mm in

dimension (Fig. 19.5). Tumors with confluent growth, by definition, have a DOI exceeding 1 mm. Confluent growth is characteristic of deeply invasive squamous cell carcinomas that are associated with stromal desmoplasia, resulting in fibrovascular stromal changes adjacent to the interconnected cords of tumor.

Compact (pushing; well-differentiated) growth is squamous tumor growth that maintains continuity with the overlying epithelium and infiltrates as a well-defined and well-circumscribed tumor mass, without islands of infiltrating tumor remote from the tumor mass. Tumors with compact growth typically have thickness of 5 mm or less and rarely invade vascular space. They are characteristically well-differentiated, with the tumor cells resembling the squamous cells of the adjacent and overlying epithelium. There is usually minimal stromal desmoplasia, although there may be a lymphocytic inflammatory cell infiltrate.

Finger-like (spray or diffuse; poorly differentiated) growth is characterized by a trabecular appearance with small islands of poorly differentiated tumor cells found within the dermis or

FIGURE 19.5. Confluent pattern of invasion. The tumor has a compact, pushing growth pattern with a well-defined tumor-dermal interface. The tumor diameter exceeds 1 cm, and has finger-like growth pattern, with small, variable-sized tumor nests within the adjacent dermis. The adjacent dermis has a desmoplastic, fibrotic appearance.

FIGURE 19.6. Finger-like growth. The tumor forms small nests surrounded by a desmoplastic stroma.

submucosa deeper than the bulk of the tumor mass. Tumors with this growth pattern are typically associated with a desmoplastic stromal response (Fig. 19.6) and a lymphocytic inflammatory cell infiltrate. In tumors with a DOI less than 5 mm, the finger-like pattern of growth is associated with a higher frequency of inguinofemoral lymph node metastasis.

In some cases, a single tumor may have both compact and finger-like growth patterns. Mixed patterns, in our experience, are more commonly encountered in frankly invasive vulvar carcinomas and are rarely seen in superficially invasive tumors. The GOG has referred to tumors with a compact pattern of growth as well-differentiated, and to tumors with the finger-like pattern of growth as poorly differentiated. Using this terminology, the GOG proposed the following grading system for vulvar squamous cell carcinoma:

- Grade 1 tumors are composed of well-differentiated tumor and contain no poorly differentiated element.
- Grade 2 tumors contain both patterns, with the poorly differentiated portions making up one-third or less of the tumor.
- Grade 3 tumors also contain both components, with the poorly differentiated portion composing more than one-third but less than one-half of the tumor.
- Grade 4 tumors have one-half or more of the tumor composed of the poorly differentiated elements.

The ISGYP Committee of Terminology for Nonneoplastic Epithelial Disorders and Tumors recommended that the following information be included in the pathology report of all excised vulvar squamous cell carcinomas, information also supported by the College of American Pathologists, and often used by tumor registries (40):

1. Depth of tumor invasion in millimeters
2. Thickness of the tumor in millimeters
3. Method of measurement of the DOI and thickness
4. Presence or absence of vascular space (lymphatic) involvement by tumor
5. Diameter of the tumor, measured from the specimen in the fresh or fixed state
6. Clinical measurement of the tumor diameter, if available

In a multivariable retrospective analysis of 39 cases of vulvar squamous carcinoma, in addition to clinical stage and when corrected for treatment modality, pattern of tumor invasion, depth of tumor invasion, and lymph node status were all found to be significant prognostic factors. In addition, dermal desmoplasia associated with tumor invasion also

had a suggestive association. Findings that did not correlate with survival were squamous cell carcinoma type, vascular space involvement by tumor, adjacent HSIL VIN, tumor nuclear grade, or associated degree of inflammatory response. DNA ploidy analysis (i.e., diploid versus aneuploid) of vulvar carcinoma does not appear to have significance in regard to survival (41).

Several histopathologic types of vulvar squamous cell carcinoma are recognized. The usual types include squamous cell carcinoma, keratinizing type; squamous cell carcinoma, non-keratinizing type; basaloid carcinoma; and warty (condylomatous) carcinoma (42). Less common types include acantholytic squamous cell carcinoma, squamous cell carcinoma with tumor giant cells and spindle cell squamous carcinoma, squamous cell carcinoma with sarcoma-like stroma, sebaceous carcinoma, verrucous carcinoma, and other rarer types (38,42).

Vulvar squamous cell carcinomas of the basaloid and warty types, as well as HSIL (VIN 2/3) of all but the differentiated type, are recognized to be associated with human papillomavirus, primarily HPV 16. The HPV can be detected within the tumor cells by a variety of techniques, including polymerase chain reaction (PCR), hybrid capture, and *in situ* hybridization. In addition, it is now recognized that approximately one-quarter ($27\% \pm 9\%$) of the women with vulvar squamous carcinoma have anti-HPV 16 antibodies expressed serologically as IgG antibodies to HPV 16 virus-like particles as measured by enzyme-linked immunosorbent assay (ELISA) (43).

Adenoid squamous carcinoma (pseudoangiosarcomatous carcinoma, acantholytic squamous cell carcinoma, pseudoglandular squamous cell carcinoma) refers to squamous cell carcinomas with pseudoglandular features. These tumors are characterized by small gland-like spaces within a tumor that otherwise appears to be a poorly differentiated squamous cell carcinoma. It is considered a highly aggressive variant of vulvar squamous cell carcinoma (44). This tumor should be differentiated from adenosquamous carcinomas that contain an obvious adenocarcinoma component (37). Adenoid squamous carcinoma does not contain sialomucin, but adenosquamous carcinoma typically does contain mucin within the adenocarcinoma component. *Squamous cell carcinoma with tumor giant cells* has multinucleated tumor giant cells intermixed within the squamous carcinoma (45). This tumor may resemble amelanotic melanoma. Squamous cell carcinoma with tumor giant cells, unlike melanoma, does not express S100 antigen, HMB45, or Melan-A on immunoperoxidase studies. This tumor does express low-molecular-weight keratin, similar to other squamous carcinomas.

Sebaceous carcinoma of the vulva. These tumors, which arise from the sebaceous glands of the vulvar skin, may be associated with VIN. This rare tumor is aggressive. The tumor cells are relatively large with large nuclei and prominent nucleoli with prominent cytoplasm. The cytoplasm, related to its lipid content, has a finely vacuolated appearance. The tumor may have the appearance of a squamous cell carcinoma intermixed with sebaceous elements. Deep invasion and lymph node or other metastasis may be present on initial presentation (46,47).

Spindle cell squamous cell carcinomas consist of poorly differentiated neoplastic epithelial cells that have an elongated spindle shape and may mimic a spindle cell melanoma or a sarcoma (Fig. 19.7) (48). Squamous cell carcinoma with spindle cell stroma is a squamous cell carcinoma associated with a sarcoma-like stromal/dermal response that may mimic a primary sarcoma (49). Spindle cell squamous cell carcinomas can be differentiated from sarcomas by immunoperoxidase techniques. Like other squamous cell carcinomas, the spindle cell variant contains keratin and lacks the antigens distinctive to sarcomas of various origin. S100 antigen, HMB45, and Melan-A are usually immunoreactive in a spindle cell melanoma and lacking in a spindle cell squamous carcinoma.

FIGURE 19.7. Spindle-cell squamous carcinoma. The tumor cells have a spindle shape and poorly defined cell junctions.

Verrucous Carcinoma

Verrucous carcinoma of the vulva typically presents as an exophytic-appearing growth that can be locally destructive. Clinically, it may resemble condyloma acuminatum. The so-called Buschke-Lowenstein giant condyloma is classified as a variant of verrucous carcinoma by the World Health Organization (30).

Microscopically, verrucous carcinoma is characterized by well-differentiated epithelial cells. The tumor growth pattern is characterized by a “pushing” tumor-dermal interface with minimal stroma between the acanthotic epithelium (Fig. 19.8). The surface is often hyperkeratotic, and there may be parakeratosis. Observed mitoses are characteristically normal. Within the dermis, a mild lymphocytic inflammatory cell response is usually seen. Vascular space involvement by tumor is characteristically lacking. Because of its excellent prognosis, strict histologic criteria should be used in the diagnosis of verrucous carcinoma. Squamous carcinomas with focal verrucous features should not be described or diagnosed as verrucous carcinoma.

FIGURE 19.8. Verrucous carcinoma. The epithelial cells are well-differentiated, and the tumor has a “pushing border” with a delicate vascular core between the epithelial elements.

Verrucous carcinomas are characteristically diploid, unlike typical squamous cell carcinomas of the vulva, which are usually aneuploid by DNA analysis. Verrucous tumors may be associated with HPV 6 or its variants (50).

The major differential diagnosis of squamous cell carcinoma includes keratoacanthomas, pseudocarcinomatous (pseudoepitheliomatous) hyperplasia, epithelioid sarcoma, and malignant rhabdoid tumor.

Basal Cell Carcinoma

Basal cell carcinoma is a relatively rare tumor in the vulva, accounting for 2% to 4% of infiltrative neoplasms. These tumors are most commonly found in elderly women (51). The surface of the tumor appears granular and is well circumscribed; on palpation, the tumor is characteristically very firm. Vulvar basal cell carcinoma most commonly arises on the labia majora and is typically 2 cm or less in diameter.

The epithelial cells composing basal cell carcinoma are typically small and vary in form, with small hyperchromatic nuclei that may exhibit some nuclear pleomorphism. These tumors may have a variety of growth patterns (e.g., trabecular, insular), although peripheral nuclear palisading is a relatively consistent finding. Basal cell carcinomas often have an intraepithelial component that is contiguous with the infiltrative component, if present.

Metatypical basal cell carcinoma is a variant of basal cell carcinoma that usually occurs at mucocutaneous junctions. The term *basosquamous carcinoma* is applied to these tumors because of their microscopic features, which include basal cell carcinoma intermixed with a squamous cell carcinoma component. Nuclear pleomorphism is usually seen in metatypical basal cell carcinoma and in the basal cell and squamous cell components of the tumor. The deeper tumor cells, close to the underlying stroma, have the greatest degree of nuclear pleomorphism and the more prominent squamous features. These tumors have a more aggressive clinical behavior than typical basal cell carcinoma.

The differential diagnosis of basal cell carcinoma includes basaloid squamous cell carcinoma, Merkel cell tumor of the skin, and metastatic small cell carcinoma. Basaloid squamous cell carcinoma can be distinguished by its lack of characteristic basal cell growth pattern, and the presence of intracellular bridges. Nuclear pleomorphism is typically much greater in basaloid squamous cell carcinoma than in basal cell carcinoma. Basal cell carcinomas express BerEP4 on histochemical study, an antigen not expressed by basaloid squamous cell carcinomas (38). Basaloid squamous cell carcinomas are typically associated with HPV 16, which is not typically associated with basal cell carcinoma. Merkel cell tumors and other neuroendocrine tumors of the vulva are typically subcutaneous or dermal nodules, and not intraepithelial lesions (see the section on neuroendocrine tumors).

Neuroendocrine and Neuroectodermal Tumors: Merkel Cell Tumors and Peripheral Neuroectodermal Tumor/Extrasosseous Ewing Sarcoma

Merkel Cell Tumor. Merkel cell tumors are neuroendocrine tumors of the skin occurring usually within the dermis. The tumor is composed of small, relatively uniform cells with little cytoplasm and hyperchromatic nuclei with a punctate chromatin pattern, and it has a high mitotic count. The tumor is infiltrative and often involves vascular spaces. Merkel cell tumors have been associated with squamous cell carcinoma and vulvar intraepithelial neoplasia (52). Merkel cell tumors are subclassified as carcinoid-like (trabecular), intermediate type, and small cell (oat cell) type. These tumors typically express neuron-specific

enolase, synaptophysin, chromogranin, and low-molecular-weight keratin. Keratin study, such as with cytokeratin 20, demonstrates a distinct perinuclear cytoplasmic dot. Dense core neurosecretory granules are seen by electron microscopy. These features differentiate it from basal cell or squamous cell carcinoma (38). Merkel cell tumors frequently have both regional lymph node and distant metastases and are associated with a poor prognosis.

Peripheral Neuroectodermal Tumor/Extrasosseous Ewing Sarcoma. Peripheral neuroectodermal tumor/extrasosseous Ewing sarcoma (PNET) is a rare neuroendocrine vulvar neoplasm that has been reported in childhood and women of reproductive age. The tumor may present as a subcutaneous or polypoid mass and clinically may resemble a cyst or be ulcerated (53,54). On microscopic examination the tumor is circumscribed and multilobulated, without capsule but nonencapsulated, and contains small cells with little cytoplasm and nuclei with hyperchromatic and finely granular nuclear chromatin. Some cells have small nucleoli, and mitotic figures are usually common, with mitotic counts from 3 to exceeding 10 per 10 high power fields. Numerous patterns of growth may be seen with highly cellular undifferentiated areas, areas with cyst formation containing eosinophilic proteinous material, rosettes with Homer-Wright rosettes, and follicle-like structures.

The cells of PNET have periodic-acid Schiff (PAS) staining cytoplasm that digests with diastase, and typically express CD99 and vimentin. Although, as in Merkel cell tumors, focal reactivity for synaptophysin and neuron-specific enolase may be present, cytokeratin reactivity is not present but may be focally immunoreactive in some cases.

Dense core neurosecretory granules, as seen in Merkel cell tumor by electron microscopy, are not present. Cytogenetic study of these PNET tumors demonstrates translocation t(11;22)(q24;q12) in approximately 90% of cases. This translocation can also be demonstrated with fluorescence *in situ* hybridization, or reverse transcriptase polymerase chain reaction (RT-PCR) (53,54).

Urothelial/Transitional Cell Carcinoma

Urothelial carcinoma may be a primary tumor of the vulva, usually arising within the Bartholin's glands. More commonly, urothelial carcinoma is metastatic to the vulva, having arisen within the bladder or urethra. In rare instances, the tumor presents as a Paget-like lesion of the vulva (see section on Paget's disease) (55).

Microscopically, urothelial carcinomas are composed of relatively uniform cells; nuclear pleomorphisms may be marked in high-grade urothelial neoplasms. The cytoplasm is eosinophilic without apparent inclusions or keratin formations, although focal keratin formation may be seen. The tumors may exhibit papillary-like growth.

Adenocarcinoma and Carcinoma of Bartholin's Glands

Most primary adenocarcinomas of the vulva arise within Bartholin's glands. Adenocarcinoma may also arise from other glands or skin appendages of the vulva, including sweat glands and Skene's glands (56). Clear cell adenocarcinoma arising in endometriosis has been reported in the groin (57). Invasive vulvar Paget's disease has given rise to adenocarcinoma (Fig. 19.13). Primary malignant tumors arising within Bartholin's glands include adenocarcinoma and squamous cell carcinoma, which occur with approximately equal frequency and account for approximately 80% of all primary malignant tumors in this site. Adenoid cystic carcinomas compose approximately 15% of all primary carcinomas, with adenosquamous carcinomas and

transitional cell carcinomas each composing approximately 5% of the primary Bartholin's gland tumors (58).

Carcinoma of Bartholin's glands generally occurs in older women and is rare in women younger than 50. In clinical practice, it is generally advisable to excise an enlarged Bartholin's gland in a woman 50 years of age or older, especially if there is no known history of prior Bartholin's cyst. If a cyst is drained and a palpable mass persists, excision is also indicated. Fine needle aspiration of a Bartholin's mass for cytologic evaluation may help to establish a positive diagnosis.

Primary carcinomas within Bartholin's glands are usually solid tumors and are often deeply infiltrative. A variety of histologic types of adenocarcinoma have been described within Bartholin's glands. Mucinous, papillary, and mucoepidermoid carcinoma tumor types have been described, in addition to adenosquamous, squamous, and transitional cell carcinoma. Adenocarcinoma of Bartholin's glands is typically immunoreactive for carcinoembryonic antigen (38). Histopathologic features that identify a carcinoma arising in Bartholin's glands include a recognizable transition from a Bartholin's gland to tumor. The histopathologic tumor type must be consistent with an origin from a Bartholin's gland, and the tumor must not be metastatic to a Bartholin's gland.

These malignancies are characteristically deep and difficult to detect in their early growth. Approximately 20% of women with primary carcinoma of Bartholin's glands have metastatic tumor to the inguinofemoral lymph nodes at the time of primary tumor diagnosis.

Adenocarcinoma Arising in Vulvar Skin Appendages

The vulvar labia majora were once thought to be within the milk line, but this has been significantly challenged by Van der Putte, who observed that the milk line did not involve the vulva in the human (59). The breast-like tumors found are believed to arise from specialized anogenital glands that reside in the intralabial sulci and may be the origin of papillary hidradenoma. Both benign and malignant breast-like tumors have been observed within the vulva (60). Fibroadenoma, intraductal papilloma, and lactating adenoma have been observed. Primary adenocarcinoma of the vulva may arise in specialized anogenital glands, which reside in the intralabial sulcus and are believed to be the origin of papillary hidradenoma of the vulva, as well as the breast-like tumors seen within the vulva, and these glands may resemble breast tissue (59,60).

Adenosquamous Carcinoma

Adenosquamous carcinomas are epithelial tumors composed of both malignant squamous and gland-forming elements. Adenosquamous carcinomas account for approximately 5% of all tumors of Bartholin's glands. These tumors may be composed of a poorly differentiated squamous component mixed with cells bearing small glandular lumens containing mucin.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma arising within the vulva most commonly arises within the Bartholin's glands and composes approximately 15% of all carcinomas of Bartholin's glands. Microscopically, adenoid cystic carcinomas are composed of relatively uniform small cells with regular, round nuclei and minimal cytoplasm. The cord-like or "nested" arrangement contains gland-like lumens that include an acellular eosinophilic material. Electron microscopy has documented that this material is basement membrane-like material rather than a secretion. These tumors are therefore more properly considered a variant of squamous cell carcinoma than adenocarcinoma.

Carcinomas of Sweat Gland Origin

Primary carcinomas of sweat gland origin are relatively rare within the vulva, composing approximately 10% of all vulvar malignant tumors. A variety of sweat gland carcinomas in this site have been described, including eccrine adenocarcinoma, eccrine porocarcinoma, and clear cell hidradenocarcinoma (56). Primary adenocarcinomas of apocrine gland origin have also been described arising within the vulva, and some of these have been associated with vulvar Paget's disease. These should be distinguished from the benign papillary hidradenoma, which typically arises in the intralabial papillary sulcus from specialized anogenital glands and contains a myoepithelial cell population, distinguishing it from adenocarcinoma (59).

Vulvar Paget's Disease and Paget-Like Lesions

Vulvar Paget's disease typically presents as an eczematoid, red, weeping area on the vulva, often localized to the labia majora, perineal body, clitoral area, or other sites. This disease typically occurs in older, postmenopausal Caucasian women, although it has been described in a premenopausal woman. Because of its eczematoid, or "cake-icing" appearance, it is not unusual for vulvar Paget's disease to be misdiagnosed as eczema or contact dermatitis. Approximately 15% of women with vulvar Paget's disease have underlying primary adenocarcinoma, usually arising within apocrine glands or the underlying Bartholin's glands (Fig. 19.9). The Wilkinson and Brown etiologic classification of vulvar Paget's disease divides Paget's disease into 2 main groups: those of cutaneous origin and those of noncutaneous origin (55). The 2 most common types of noncutaneous Paget's disease are those associated with colorectal adenocarcinoma and those associated with bladder urothelial carcinoma. Women with Paget's disease of the colorectal type usually present with a lesion that involves the perianal skin, and this lesion is a manifestation of underlying colon or rectal adenocarcinoma. Women with Paget-like disease (Pagetoid urothelial intraepithelial neoplasia [PUIN]) typically present with a lesion involving the periurethral area and vulvar vestibule (55,61,62). In these cases there is associated bladder and/or urethral urothelial carcinoma with the extension of the neoplastic urothelial cells to the epithelium of the vulva (55,61). In cases of PUIN, total deep vulvectomy is not indicated because there is no associated underlying cutaneous adenocarcinoma. The tumor cells are from the bladder and/or urethra, representing an intraepithelial transitional cell

FIGURE 19.9. Paget's disease. The large cells with prominent cytoplasm and large nuclei represent the intraepithelial Paget's cells. A few small gland-like intraepithelial structures are formed by the Paget's cells.

neoplasm extending from the bladder and/or urethra (55). These cells have been reported from a vaginal cytology specimen from a woman with a PUIN lesion (63).

Cutaneous Paget's disease is most commonly a primary intraepithelial neoplasm. In such cases the intraepithelial Paget's disease may have an associated invasive Paget's disease. In rare cases, cutaneous Paget's disease may be a manifestation of an underlying cutaneous adenocarcinoma (55). Cutaneous Paget's disease is characterized by the presence of Paget's cells, which are found within the involved epithelium. A Paget's cell is relatively large, with a prominent nucleus that typically has coarse chromatin and a prominent nucleolus. On hematoxylin and eosin staining, the cytoplasm is distinctly pale compared with the surrounding keratinocytes. The cytoplasm may be vacuolated or appear foamy and typically is somewhat basophilic (Fig. 19.9).

Paget's cells of cutaneous origin are rich in carcinoembryonic antigen (CEA), which can be identified with immunoperoxidase techniques (55). Paget's cells also express cytokeratin 7 (CK-7) and gross-cystic-disease fluid protein-15 (GCDFFP-15) (55,64). Paget's cells infrequently express CA-125, and estrogen receptor is generally negative (65). Immunohistochemical study for CK-7 is useful in many cases to identify the Paget's cells that are strongly CK-7 positive, whereas the adjacent epithelial cells are negative (66). Invasive Paget's disease 1 mm or less in DOI has reportedly little risk for recurrence (65).

The differential diagnosis of Paget's disease of cutaneous origin includes PUIN/Paget's disease of urothelial origin, Paget's disease of colorectal origin/or other related adenocarcinoma, superficial spreading malignant melanoma, pagetoid reticulosis, and the pagetoid variant of vulvar intraepithelial neoplasia, which are keratinocytic cells resembling Paget's cells. These can all be differentiated by immunoperoxidase techniques because melanomas do not express cytokeratin, but usually express S100 protein, HMB45, and Melan-A, which are absent in Paget's cells (55,67). The Paget-like cells in PUIN express uroplakin-3, but do not express GCDFFP-15. Adenocarcinoma cells of colonic, anal, or rectal origin express CEA, as well as caudal homeobox (CDX), whereas Paget's disease of cutaneous origin does not express CDX. HSIL (VIN 3) of pagetoid type may microscopically resemble Paget's disease or melanoma, but the cells of LSIL or HSIL (VIN 1-VIN 2-3) do not express CEA, S100, or melanoma antigen (55,61).

Vulvar Malignant Melanoma

Malignant melanoma of the vulva accounts for approximately 9% of all primary malignant neoplasms on the vulva, and vulvar melanoma accounts for approximately 3% of all melanomas in women. This tumor occurs predominantly in Caucasian women, with approximately one-third of the cases occurring in women younger than 50, and the mean age at diagnosis is 55 years (68). The peak frequency occurs between the sixth and seventh decades, and the highest incidence is in women 75 years of age or older, where the age-specific incidence is reported to be 1.28 per 100,000 (69). The most common presenting symptom is bleeding; however, pruritus, pain, dysuria, and a palpable mass may all be symptoms (69,70,71). The tumor may arise from a preexisting pigmented lesion or from normal-appearing skin. The primary site on the vulva may be the clitoris, labia minora, and labia majora, where melanomas occur with approximately equal frequency (72). The tumor may be elevated, nodular, or ulcerated. Although tumors are usually pigmented, approximately one-fourth are nonpigmented, amelanotic melanomas, a melanoma type that clinically and pathologically may resemble squamous carcinoma. In the clinical setting, the differential diagnosis includes pigmented condyloma acuminatum, pigmented HSIL VIN, atypical genital nevus, large vulvar nevi, melanosis of the vulva, or other malignant tumors, including malignant soft-tissue tumors (61,73).

Vulvar malignant melanomas may be subclassified into 3 specific categories: superficial spreading malignant melanoma, nodular melanoma, and mucosal lentiginous melanoma, which is also referred to as mucosal/acral lentiginous melanoma (74). In the vulva, some cases are mixed or cannot be specifically classified. Mucosal lentiginous melanomas are the type most commonly reported on the vulva, accounting for over one-half of the cases in larger series (69,74). Nodular melanomas are second in frequency, accounting for approximately one-fifth of the cases, and have the overall worst prognosis of the melanoma types, usually related to the greater thickness and deeper invasion at the time of presentation. Superficial spreading melanomas are the least common type in the vulva. Some variation in the frequency of these types in the vulva is present in the literature, primarily related to some variations in pathologic classification (68–72,74,75,76).

Histopathologic differentiation of melanoma type is based on identification of a superficial spreading component. Mucosal lentiginous melanomas have the neoplastic melanocytes clustered in the dermal-epithelial junction and have both radial growth and vertical growth. Superficial spreading melanomas have radial growth involving 4 or more rete lateral to their vertical or infiltrative growth (61). Nodular melanomas show minimal or no radial growth. Superficial spreading malignant melanoma characteristically shows junctional melanocytes with radial growth, and a vertical growth pattern may be absent. The tumor cells are highly variable in appearance but commonly are relatively large, with nuclei showing minimal variation in size and containing prominent nucleoli (Fig. 19.10). These cells may

FIGURE 19.10. Malignant melanoma. The tumor is within the dermis and contains dark melanin pigment. Junctional growth is seen within the overlying epithelial dermal junction.

or may not contain pigment. The form of the cells ranges from epithelioid to spindle shaped; in some cases, the spindle cell type may predominate. The spindle cells may be relatively small, with oval nuclei and elongated cytoplasm. They may infiltrate the adjacent dermis in cords and sheets.

Malignant melanomas typically express S100 antigen, HMB45, and Melan-A and lack cytokeratin or CEA. The microscopic differential diagnosis for superficial spreading malignant melanoma is primarily vulvar Paget's disease, pagetoid reticulosis, and Kaposi's sarcoma. Immunohistochemical techniques are essential in discriminating superficial spreading melanoma from Paget's disease (see the section on vulvar Paget's disease) (67). Nonpigmented nodular melanomas may mimic squamous cell carcinoma or spindle cell neoplasms of various types. In these circumstances, immunoperoxidase procedures are of great value, because squamous cell carcinomas typically do not express S100 protein, HMB45, or Melan-A, and melanomas do not express cytokeratin (63).

Tumor thickness is the most important measurement in evaluating malignant melanoma (68). The Clark level definitions describe the extent of dermal and subcutaneous involvement by the melanoma (77). Measurements for vulvar melanomas can be applied as for skin and mucous membranes, as described by Breslow (78). With the Breslow method, the thickness measurement for cutaneous melanomas requires measurement from the top of the granular layer to the deepest point of invasion. Malignant melanomas that have a thickness of up to 1 mm are generally considered of minimal risk of recurrence. Melanomas at Clark level 2 or thickness of 1.49 mm or less, or tumor volume of 100 mm³, also correlate with good prognosis (79). A poor prognosis is correlated with Clark level 5, thickness >2 mm, or mitotic count exceeding 10/mm². Other prognostic factors include mitotic rate and reaction and surface ulceration (80).

Vulvar melanoma has been described as being associated with NRAS codon 12 mutation, as more commonly seen in sun-exposure-related melanomas; however, most mucosal non-sun-exposure-related melanomas do not express NRAS exon 2 mutations (81).

Melanomas arising in the vulva may metastasize to other sites within the lower female genital tract, including the cervix, vagina, urethra, and rectum. Distant metastasis is common with disseminated disease. Survival after recurrence is poor: approximately 5%.

Vulvar Sarcomas

Leiomyosarcoma. Leiomyosarcoma is the most frequent primary vulvar sarcoma. It most commonly arises in the labia majora or Bartholin's gland area, although these smooth muscle tumors may arise in the clitoris and labia minora. The tumors are generally larger than 5 cm in diameter when first diagnosed and may be deep within the subcutaneous tissue.

On microscopic examination, these tumors are composed of interlacing spindle shaped cells, sometimes with an epithelioid appearance. Features of leiomyosarcoma include an infiltrating border and metastasis. Microscopic criteria for diagnosis require determination of the mitotic figure count. In cases with minimal pleomorphism, it is generally accepted that the diagnosis of leiomyosarcoma can be made with a mitotic count of 10 or more per 10 high power fields. Tumors that have an infiltrating border or nuclear atypia with pleomorphism and mitotic count of 5 or more per 10 high power fields are classified as leiomyosarcoma. There are tumors that may show no significant atypia, have a diameter exceeding 5 cm, have an infiltrating margin, and have a low mitotic count, up to 5 per 10 high power fields. It is preferable to classify them as smooth muscle tumors of uncertain malignant potential, because the risk of recurrence is uncertain (38,82,83).

Malignant Fibrous Histiocytoma. Malignant fibrous histiocytoma (MFH) arises from histiocytes with fibroblastic differentiation. It is considered the second most common sarcoma of the vulva and has its peak frequency in middle age. MFH typically presents as a solitary mass that may appear somewhat brownish or pigmented, secondary to areas of focal hemorrhage within the tumor.

On microscopic examination, the tumor is characterized by a complex interlacing cellular growth pattern with marked nuclear pleomorphism, including multinucleated cells and large bizarre cells. Abnormal mitotic figures may be apparent. Microscopic variants of this tumor include inflammatory, giant cell, myxoid, and angiomatoid types (57,84). On immunoperoxidase study, these tumors contain α_1 antitrypsin and α_1 antichymotrypsin. MFH is typically infiltrative, with infiltrative margins, and may involve the underlying fascia. Involvement of the fascia is associated with a higher risk of local spread and distant metastasis.

Epithelioid Sarcoma. Epithelioid sarcoma may arise within the labia majora, subclitoral area, and clitoris (85). Its microscopic features may resemble squamous carcinoma, malignant melanoma, malignant rhabdoid tumor, or lymphoma. Epithelioid sarcoma is usually relatively superficial, arising in and involving the reticular dermis, but it may occur in deeper structures.

On microscopic examination, the tumor is nodular and may have areas of necrosis. The tumor cells have an epithelioid appearance with eosinophilic cytoplasm, but there may be metaplastic components, including cartilage and bone. On immunohistochemistry, this tumor contains cytokeratin, which does not distinguish it from epithelial tumors, but is of value in differentiating it from malignant melanoma or other types of soft-tissue tumors. Epithelioid sarcoma rarely metastasizes, although local recurrence is a risk. The differential diagnosis for this tumor includes squamous cell carcinoma, malignant melanoma, lymphoma, and malignant rhabdoid tumor, all of which are capable of distant metastasis and aggressive behavior (85). Immunoperoxidase studies are of value in differentiation but have not been of value in differentiating epithelioid sarcoma from malignant rhabdoid tumor. The distinction of these 2 tumors is based primarily on microscopic features.

Malignant Rhabdoid Tumor. Malignant rhabdoid tumor has been described in the vulva and, like epithelioid sarcoma, may be relatively superficial and contain tumor cells with an epithelioid appearance with eosinophilic cytoplasm. Unlike epithelioid sarcoma, malignant rhabdoid tumors have relatively pleomorphic nuclei. Metaplastic elements are usually not present. Malignant rhabdoid tumor also has eosinophilic cytoplasmic inclusions, which are not present in epithelioid sarcoma. These inclusions give some of the cells the appearance of signet ring cells. Malignant rhabdoid tumor has a lobulated architecture but lacks necrosis or granulomatous features, which are often found in epithelioid sarcoma (82,83,85).

Yolk Sac Tumor

Yolk sac tumor (endodermal sinus tumor) is a rare germ cell tumor of the vulva, primarily arising in the labia or clitoral areas (38,86). The age range of patients is from just under 2 to 26 years. Distinctive microscopic features are similar to endodermal sinus tumor in the ovary, including the Schiller-Duval bodies, distinctive eosinophilic globules that are PAS positive and contain α -fetoprotein, and the presence of α -fetoprotein within the tumor, as demonstrated by immunoperoxidase technique.

Other Sarcomas and Soft-Tissue Tumors

A partial list of primary sarcomas of the vulva includes angiosarcoma, Kaposi's sarcoma, hemangiopericytoma, rhabdomyosarcoma, alveolar soft part sarcoma, and liposarcoma. Sarcoma botryoides is a variant of rhabdomyosarcoma that may involve the vulva, but most cases arise within the vagina or base of the bladder. Kaposi's sarcoma and angiosarcoma should be differentiated from bacillary angiomatosis, which is a benign pseudo-neoplastic infectious process (87).

Aggressive angiomyxoma is well-documented as a primary soft-tissue tumor of the vulva and pelvis that occurs predominantly in women of reproductive age. It is locally aggressive but rarely metastatic (82,88). It typically presents as a deep soft-tissue mass or pelvic mass, sometimes mimicking a Bartholin's cyst or inguinal hernia. In the pelvis, it may displace other pelvic organs and may be best appreciated on radiologic studies.

The tumor is typically poorly circumscribed and difficult to discriminate from adjacent soft tissue. On microscopic examination, the tumor has many blood vessels. The tumor consists predominantly of spindle to stellate shaped cells, with relatively small uniform nuclei representing predominately fibroblasts and myofibroblasts. Mitotic figures are very rare. The tumor stroma varies from myxoid to densely collagenous. Nerves, small glandular structures with mucin-secreting columnar cells, and other epithelial elements may be found trapped within the tumor. The differential diagnosis is as for angiomyo-fibroblastoma (AMF), summarized below.

AMF is a rare, benign tumor of soft-tissue origin that occurs predominantly in the female genital tract (89). When involving the vulva, it usually presents as a soft subcutaneous mass, but may occasionally be pedunculated (89).

On microscopic examination, the tumor usually has well-demarcated borders. Variable cellularity is present with an edematous appearance. The cells are spindle shaped, plasmacytoid or epithelioid in appearance, and mitotic figures are rare. Cells were present in most cases. Cells may be clustered about blood vessels. The tumor is vascular with small to medium sized vessels. Some inflammatory cells, commonly lymphocytes or mast cells, may be seen around the vessels.

The differential diagnosis includes aggressive angiomyxoma, atypical myxoid fibroepithelial stromal polyp, Bartholin's cyst, lipoma, and leiomyoma. The reader is referred to additional texts on these and other soft-tissue tumors of the vulva (38,82,83).

Metastatic Tumors to the Vulva

Most metastatic tumors to the vulva involve the labia majora or Bartholin's glands. In the vulva, they usually present as single or multiple intradermal or subcutaneous nodules but may present as a Bartholin's gland mass (58,90,91,92). Metastatic tumors account for approximately 8% of all vulvar tumors, and in approximately one-half of the cases the primary tumor was in the lower genital tract, including the cervix, vagina, endometrium, and ovary. Cervical carcinoma is the most common origin of contiguous metastasis. Local metastasis secondary to contiguous involvement of the vulva from urothelial carcinoma of the bladder or urethra, or anorectal carcinoma, may involve the vulva and present as a Paget-like lesion (see Paget's disease and Paget-like lesions in this section) or a vulvar or groin node mass (55,93). Remote metastases have been observed from tumors arising in breast, kidney, stomach, lung, and other sites. Malignant melanoma and neuroblastoma can also metastasize to the vulva, as can gestational choriocarcinoma and malignant lymphomas. In approximately 10% of the cases, the primary site of the metastatic tumor cannot be identified.

PROGNOSTIC FACTORS (INFLUENCING CHOICE OF TREATMENT)

Prognostic information collected during the diagnostic work-up of squamous cell carcinomas of the vulva serves as a basis for both patient counseling and treatment decisions. Fundamental decisions regarding goals of therapy (cure vs. palliation) and sequencing of primary treatment (primary surgery vs. chemoradiation) should be based on 4 things: (a) historical and demographic risk factors; (b) characteristics of the primary tumor, including location, laterality, size (cm), DOI, and lymphovascular space invasion; (c) clinical $\pm$ radiographic assessment of the inguinal lymph nodes; and (d) The probability of distant metastatic disease.

After resection of the primary tumor and surgical evaluation of the inguinal lymph nodes, additional information obtained from intraoperative observations and the final pathologic specimens serve to guide decisions regarding adjuvant therapy. The most important prognostic factors for the adjuvant management of squamous cell carcinoma of the vulva have been incorporated into the FIGO and AJCC staging systems (Table 19.2). Among the many factors that affect recurrence risk and disease-specific mortality, *nodal status, particularly the number of positive nodes, size of the largest metastasis, and the presence or absence of extracapsular extension, are the most important*. Each of the above risk factors will be discussed below in relation to its temporal presentation (pre- vs. postsurgical resection). Prognostic factors associated with the resection specimen and inguinal lymph node evaluation following surgery are also discussed below.

Presurgery

DOI, tumor size, and lymphovascular space invasion are the primary determinants of a patient's risk for nodal metastases, and the presence of nodal involvement is the single most important determinant of disease-specific mortality. Multiple studies have demonstrated a direct correlation between lymphovascular space invasion, increasing stromal invasion and the presence of involved inguinal lymph nodes (6,22,94,95,96).

Postsurgery

Following surgery, intraoperative findings and final pathologic analysis are used to estimate recurrence risk and subsequently guide decisions regarding adjuvant therapy. Among the many pathologic findings (in addition to tumor size, lymphovascular space invasion, and DOI) that have been shown to affect recurrence risk, surgical nodal status is the most important (22,94,95).

Risk of local recurrence, although associated with tumor size and extent, is also related to the adequacy of the surgical resection margins. Heaps et al., in their analysis of formalin-fixed tissue specimens, were able to demonstrate a sharp rise in the incidence of local recurrence for tumors with microscopic margins less than 8 mm (97). They suggested that this would correspond to a minimum margin of 1 cm in fresh, unfixed tissue. These observations were confirmed in a retrospective multivariate analysis of clinical data by Chan et al., who showed that pathologic margin distance ≤ 8 mm is an important predictor of local recurrence (98). De Hullu et al. reported 9 local recurrences among 40 patients with tumor-free margins ≤ 8 mm compared to no local recurrences among 39 patients with margins > 8 mm (99). To aid the surgeon in planning surgical margins of resection, Hoffman et al. measured the radial occult microscopic spread of tumor in patients with invasive squamous cell carcinoma of the vulva. They found that the gross and microscopic peripheries of

most cancers were approximately the same; however, ulcerative tumors with an infiltrative pattern of invasion were more likely to extend beyond what is grossly apparent (100).

The single most important prognostic factor for recurrence and overall survival in women with vulvar cancer is metastasis to the inguinal lymph nodes; most recurrences will occur within 2 years of primary treatment (101). The presence of inguinal node metastasis portends a 50% reduction in long-term survival (102,103). A number of noninvasive imaging modalities have been studied for the evaluation of inguinofemoral lymph node metastasis, including MRI, CT, PET, SPECT, and ultrasound. There currently is no imaging modality with a sufficiently high negative predictive value to allow for exclusion of surgical groin lymph node evaluation (104,105).

GENERAL MANAGEMENT

General Management (By Stage, Including Algorithms)

Historical Background

Development of the radical vulvectomy with bilateral inguinofemoral lymphadenectomy during the 1940s and 1950s was a dramatic improvement over prior surgical options and greatly enhanced survival, particularly for women with smaller tumors and negative lymph nodes (106,107). The ability to successfully resect vulvar tumors eliminated prolonged survival marked by local and regional progression of disease and associated pain, drainage, and bleeding. Long-term survival of 85% to 90% can now be routinely obtained with radical surgery. However, radical surgery can be associated with postoperative complications such as wound breakdown and lymphedema. Indications for radical vulvectomy and bilateral inguinofemoral lymphadenectomy for the primary treatment of vulvar cancer are very rare.

Presently, smaller vulvar tumors can be acceptably managed by less radical surgical approaches, and many authors have proposed more limited resections for certain subsets considered to represent early or low-risk disease (49,108,109,110). Advantages of such an approach are retention of a significant portion of the uninvolved vulva, preservation of body image and sexual function, less operative morbidity, and fewer late complications. In contrast, radical surgery is frequently ineffective in curing patients with bulky tumors or positive groin nodes. Multimodality programs that incorporate radiation, surgery, and chemotherapy have now been validated in women with high-risk tumors, based upon success with similar approaches in women with squamous cancers of the cervix and anus (111,112–115).

Sentinel Inguinal Lymph Node Biopsy

The SLN is defined as the first draining lymph node of a tumor. The SLN is identified by lymphatic mapping. This is a peritumoral injection of a material that is taken up by superficial cutaneous lymphatic channels and transported to the SLN. A vital blue dye or radiocolloid can be used and the SLN identified by direct visualization or detection of low levels of radioactivity by a handheld device or imaging study (Figs. 19.11 and 19.12). The modern SLN concept was first described by Morton and colleagues (116) in patients with cutaneous melanoma and shortly thereafter in patients with vulvar cancer (117). Preliminary experience with both intraoperative lymphatic dye and radioisotope injections confirmed that the SLN of the vulva is always in the groin and can be identified in most patients (118,119,120). This early experience supports the concept that

FIGURE 19.11. Transdermal localization of sentinel node using a handheld gamma counter. The probe has a collimator and is pointed away from the primary tumor. Radioactivity will fall off rapidly until the sentinel node is encountered. Mark the site of an increase in activity.

FIGURE 19.12. A hot blue sentinel node identified through a small incision. Frozen section is requested only if the sentinel node is grossly suspicious. Immunohistochemical staining is performed if the routine hematoxylin and eosin staining does not reveal metastatic disease. After a sentinel node is removed, the wound is explored with the gamma counter to assure that there is not another sentinel node in the field.

the assessment of lymphatic metastases may ultimately be reduced to the biopsy of one or 2 identifiable nodes.

Based on these early results, 2 large multi-institutional trials were initiated to determine the utility of sentinel lymph node biopsy (SLNB) in women with vulvar cancer. The GROINS V trial used a prospective, observational design, enrolling 403 evaluable women with tumors ≤ 4 cm who underwent SLNB alone. Of these, 276 women had a negative SLNB and were closely observed for recurrence during a 2-year follow-up period. Eight patients (2.9%) suffered a groin relapse. When patients with multifocal primary tumors were removed from the analysis, the relapse rate was only 2.3% (121).

The second study, GOG 173, employed a validation design. All women underwent SLNB followed by unilateral or bilateral inguinofemoral lymphadenectomy. Five hundred and fifteen women were enrolled, and 418 were evaluable. If the primary

tumor was more than 2 cm from the midline, a unilateral SLNB and inguinofemoral lymphadenectomy were performed. If the tumor was within 2 cm of the midline, or involving the midline, bilateral inguinal lymphadenectomies were performed. The false-negative rate was 8.3%, and the false-negative predictive value (FNPV) was 3.7% for the entire cohort. The FNPV is a prediction of the chance of a positive nonsentinel lymph node when the SLN is free of tumor and a lymphadenectomy has not been performed. In GOG 173 the FNPV by groin was 2.7%; for patients with tumors less than 4 cm, it was 2.0%. This means that a patient with a tumor less than 4 cm, no palpable lymph nodes, and a negative SLNB has a 2% chance of a groin relapse (122). The results of these studies indicate that, for well-selected women in the care of a surgeon experienced with this technique, the risk of groin relapse following a negative SLNB is 2% to 3% (Table 19.4). This compares favorably with superficial inguinal lymphadenectomy,

Table 19.4 SLNB Sensitivity Analysis

Analysis	SLNB Result	Present	Absent	Total	Sensitivity	90% CI	NPV (%)	90% CI	FNPV (%)	90% CI
By patients	Positive	121	0	121						
	Negative	11	286	297						
	Total	132	286	418	91.7	86.7–95.3	96.3	93.9–97.9	3.7	2.1–6.1

as reported by Stehman et al. for the GOG (123). As with all surgical innovations, individual practitioners must use care when implementing new procedures. Gynecologic oncologists can learn the procedure from peers or from surgical oncologists treating melanoma or breast cancer patients. Prior to adopting this as his / her standard, each gynecologic oncologist should determine his/her own false-negative rate by performing SLNB followed by inguinofemoral lymphadenectomy in approximately 10 cases. Some practices see very few vulvar cancer patients, in which case referral is appropriate. Considered together, the GROINS V and GOG 173 trials strongly support an assertion that, under the appropriate circumstances, SLNB should be offered to eligible women with vulvar cancer.

It is important to note that the SLN undergoes pathologic ultrastaging with serial sectioning and immunohistochemical staining if routine hematoxylin and eosin staging does not reveal metastatic disease. In most studies, including GOG 173 and GROINS V, approximately half of the lymph node metastases are detected by IHC. SLNB has the promise of reducing the number of unnecessary lymphadenectomies performed in node-negative women while at the same time identifying additional women who may benefit from adjuvant therapy.

The combination of local vulvar resection and SLNB holds the promise of improved outcomes for many women with vulvar cancer. Preservation of sexual function and body image, a reduction in the risk of lymphedema, and more focused use of adjuvant therapy are all possible.

Patients with Clinical Stage I/II Tumors at Presentation

Tumors demonstrating a DOI of the vulvar stroma of 1 mm or less (≤ 1 mm) have minimal risk for lymphatic dissemination. Excisional procedures that incorporate a 1-cm normal tissue margin are likely to provide curative results (124). Patients in this category represent the only subset for whom surgical evaluation of the inguinal lymph nodes can be omitted. These so-called superficially invasive carcinomas tend to arise in younger patients with intraepithelial squamous lesions (VIN) that are commonly associated with oncogenic HPV infections. Occult invasion in lesions thought to be intraepithelial is common (125,126). Consequently, the entire lower genital tract and vulva should be carefully evaluated before surgical resection of these lesions is attempted. The risk of vulvar recurrence or development of a new lesion at another vulvar site is significant. After primary therapy, these patients should undergo frequent follow-up examinations.

Management of clinical stage I and II vulvar cancer includes wide radical excision of the primary tumor with unilateral or bilateral SLNB plus or minus inguinofemoral lymphadenectomy. The operation removes the primary tumor with a wide radial margin of normal skin (2 cm), along with a deep margin to the deep perineal fascia; thus, the vulvar specimen will contain tumor, skin, subcutaneous fat, vascular perforators and dermal lymphatics. This approach provides excellent long-term survival and local control in approximately 88% of patients (127). Every attempt should be made to preserve structures such as the clitoris and urethral meatus. Deep margins are rarely a problem except on the perineum, where there is little or no subcutaneous fat. In this case, removal of the capsule of the anus or some of the sphincter muscle itself can be performed without a loss of anal function.

Closure of vulvar defects for small primary tumors can usually be achieved with simple mobilization of the skin and fat surrounding the vulva. In cases where primary closure is not possible, any one of a number of plastics closures are useful (discussed later). Consultation with a plastic surgeon in such cases can be invaluable.

A subanalysis of GOG 173 data also provides guidance regarding when unilateral groin evaluation is safe. GOG 173 required bilateral lymph node evaluation except when the tumor

was more than 2 cm from a midline structure. There were 234 women enrolled on GOG 173 who had a preoperative lymphoscintigraphy (LSG) and at least one SLN identified during surgery. There were 105 women with midline primary tumors and 32 women had unilateral drainage on preoperative LSG. Four of these patients had lymph node metastases on the side that did not have LSG drainage. There were 65 women with tumors located within 2 cm of the midline but not directly involving a midline structure. Twenty-seven women (42%) had unilateral drainage on LSG and bilateral surgical groin evaluation. None of these patients had metastases to the side without LSG drainage. These data support the time-honored oncologic surgical experience that midline tumors can have bilateral drainage and a unilateral LSG should not result in omission of one side. Conversely if the tumor looks lateralized and that is confirmed by LSG, unilateral SLNB is appropriate (128). The authors routinely obtain preoperative LSG, preferably by SPECT/CT (Fig. 19.16), regardless of the location of the primary, since it helps confirm the location of the SLN and the lymphatic drainage pattern.

The survival for women with adequate resection of a primary squamous carcinoma limited to the vulva and with negative nodes is 90% or better. Stage II patients who have negative margins and nodes but involvement of the lower vagina or urethra should obtain similar results.

Clinical Stage III and IV Cancers at Presentation

Some women have lymph node metastases detected by preoperative physical examination or diagnostic imaging or at the time of their primary surgery. If a node is grossly involved at this point, most gynecologic oncologists will proceed with inguinofemoral lymphadenectomy on the assumption that there is a high likelihood of additional positive lymph nodes.

Clinical stage II/III tumors often extend to adjacent mucosal structures $\pm$ the inguinal lymph nodes. Many are bulky; however, some are of limited volume but are considered high stage because of proximity to critical midline structures. Some primary tumors can be curatively excised by radical vulvectomy or by some variation of pelvic exenteration and vulvectomy. Surgical resection of 1 to 1.5 cm of the distal urethra in order to achieve a negative surgical margin does not appear to compromise bladder continence (128). Though radical surgery is an option for patients with locally advanced tumors, contemporary therapeutic strategies have centered upon sequenced radiotherapy or radiochemotherapy followed by radical surgery as a means to preserve either urinary or fecal continence or both. Vulvar cancers are sufficiently sensitive to therapeutic radiation such that function-sparing operations are feasible in selected patients with advanced disease who receive combined modality treatment (129). For patients with stage IVA tumors, similar experiences have been reported; ultraradical (exenterative) resections may also be considered for selected patients. Although occasional cures have been described with innovative combinations of surgery, radiation, and radiochemotherapy, treatment of patients with stage IVB vulvar cancer should be considered palliative.

Node-Positive Cancers

An optimal management strategy for clinically apparent node-positive patients is yet to be defined. Two factors impact management of regional disease: radiation can have a significant impact on sterilizing or eradicating small volume nodal disease, and surgical resection of bulky nodal disease also improves regional control and probably enhances the curative potential of irradiation. In multivariate analysis, Hyde et al. found that, for

patients with clinically positive groin nodes who underwent surgery followed by radiation therapy, the method of surgical groin node dissection (nodal “debulking” versus full groin dissection) had no prognostic significance (130).

Patients who undergo bilateral inguofemoral lymphadenectomy as initial therapy and are found to have positive nodes—particularly more than one positive node—are likely to benefit from postoperative irradiation to the groin and lower pelvis (131,132). Radiotherapy is superior to surgery in the management of patients with positive pelvic nodes. The morbidity of combining superficial and deep inguinal lymphadenectomy with radiation may be substantial. The highest incidences of chronic groin and extremity complications, primarily lymphedema, are seen in such cases (132).

Several management options are available for patients found to have positive nodes during the course of an inguinal lymphadenectomy when performed as a staging procedure: (a) no further surgical therapy may be performed; (b) the lymphadenectomy can be extended to include the ipsilateral deep nodes, the contralateral groin nodes, or both; or (c) postoperative irradiation can be added to any of these surgical options. Given the heterogeneity of vulvar cancer presentations, treatment individualization is necessary. If postoperative radiotherapy to the inguinal nodes ultimately is deemed to be necessary, it would be reasonable to limit resection to grossly positive nodes. Here the intent would be to minimize the likelihood of lymphedema following combined radical surgery and radiation. Excellent local control and minimal morbidity have been achieved when selective inguinal lymphadenectomy and tailored postoperative adjuvant therapy were administered to carefully selected patients (127).

The ideal management for a patient with a microscopically positive SLN who did not have a full lymphadenectomy at her primary surgery is unknown. This is the question being investigated in the GROINS VII/GOG 270 trial. In this trial, women with a negative SLN are observed, women with a metastasis ≤ 2 mm receive postoperative radiation therapy, and women with larger metastases are managed with inguofemoral lymphadenectomy and radiotherapy. Concurrent radio-sensitizing cisplatin is optional. Until these results are reported, uncertainty will remain about the management of SLNB positive patients.

Recurrent Cancer

Regardless of initial treatment, vulvar cancer recurrences can be categorized into 3 clinical groups: local (vulva), groin, and distant. The reported experience with local recurrence at the vulva is surprisingly good. Recurrence-free survival can be obtained in up to 75% of cases when the recurrence is limited to the vulva and can be excised with a gross clinical margin (133,134). The observation that many of these vulva recurrences occur at sites remote from the initial primary tumor or that they occur years after apparently successful primary treatment suggests that some recurrences probably represent new primary tumors rather than the development of new disease. Recurrences in the groin, however, are almost universally fatal. A few patients may be saved by resection of bulky disease and local radiation, perhaps even using intensity modulated radiotherapy (IMRT) in patients who have had prior pelvic radiation. Patients who develop distant metastases are candidates for palliative systemic cytotoxic or targeted chemotherapy or transition to comfort care.

Nonsquamous Histologies

Because nonsquamous vulvar malignancies are exceedingly rare, relatively little definitive information is available regarding optimal treatment and long-term outcome. Most available information is derived from isolated case reports or small series spanning long periods of time.

FIGURE 19.13. Nodular, darkly pigmented malignant melanoma of the left labium majus.

Malignant Melanoma

Malignant melanoma is the second most common vulvar malignancy, and it is most commonly seen in postmenopausal Caucasian women. Typical presentations include either an asymptomatic pigmented lesion identified during a routine exam or pruritic or painful vulvar mass (Fig. 19.13) (135). A definitive diagnosis is established by biopsy. Immunohistochemical staining for melanoma-specific antigen and S100 may be helpful in uncertain cases. Melanomas may arise from existing pigmented vulvar lesions or as new isolated primary tumors. Consequently, any pigmented vulvar lesion should be considered for biopsy. Cutaneous melanoma has evolved significantly over the past 45 years. Because of the rarity of vulvar melanoma, it has not been clear whether extrapolation of prognostic and treatment data from cutaneous nonvulvar disease is appropriate for vulvar melanoma patients. Thus, until recently multiple authors have described their experience with vulvar melanoma using one or more different staging systems (e.g., Breslow's depth, Clark's levels, AJCC staging), making standardization of prognostic groups and treatment strategies difficult. Recently, Moxley et al. reported a multi-institutional retrospective examination of 77 patients with vulvar melanoma. Presenting staging data (via AJCC, Breslow's thickness, and Clark's levels) and treatments were correlated with outcomes, specifically recurrence and overall survival. Among the 3 staging methods, only AJCC staging was significantly correlated with overall survival, although Breslow's thickness was significantly associated with likelihood of recurrence (34).

The primary treatment modality for vulvar melanoma is surgical excision. Radical vulvectomy with bilateral inguofemoral lymphadenectomy has been the historical treatment of choice (136,137). Because most failures are distant though, radical local resection does not appear to enhance survival. Furthermore, many patients with vulvar melanoma are elderly, with coexisting medical problems, making less radical and morbid surgery compelling. More recent reviews recommend some form of hemivulvectomy or wide local excision along with inguinal lymphadenectomy or SLN mapping (34,110,137). DOI and the presence of ulceration are significant prognostic factors and should be considered in treatment planning. Look et al.

reported a series of vulvar melanoma patients in whom none of the patients with lesion depth of ≤ 1.75 mm experienced a recurrence and suggested that these patients could be treated with wide local excision. In contrast, all patients with lesion depth of > 1.75 mm recurred despite radical tumor excision (75). Based on information derived from large series of patients with cutaneous melanomas at nongenital sites, regional lymphadenectomy should probably be considered a prognostic rather than a therapeutic procedure. In a multivariate analysis of 644 patients with vulvar melanoma, Sugiyama et al. reported 5-year disease-specific survival rates of 68%, 29%, and 19% for patients with zero, one, and 2 or more positive lymph nodes, respectively (135). Lymphadenectomy can be avoided in patients with superficial melanomas (< 1 mm, Tis, and Clark's level I), for whom the risk of metastatic disease is negligible. SLN identification and biopsy have been increasingly applied to the surgical management of cutaneous malignant melanomas, and multiple authors assert that for those surgeons who are competent with the technique, SLN mapping and biopsy should be considered a standard practice, with false-negative rates extrapolated from squamous carcinoma of the vulva comparable to other disease sites such as breast cancer and cutaneous, nonvulvar melanoma (34,138).

Radiation therapy may be useful in enhancing local and regional control for some high-risk patients. Despite reported complete clinical response rates and local tumor control rates of 50% to 70% for patients with localized recurrences treated with radiation therapy, alone or in combination with hyperthermia, these modalities have rarely been used in the primary treatment of vulvar melanoma (139,140).

Systemic chemotherapy, in either an adjuvant or salvage setting, is considered palliative; durable responses are rare, and adverse effects are usually considerable. Interferon alpha-2b has been shown to have activity in patients with small volume tumor burden; however, because of its narrow therapeutic index, its use is typically available only at high volume centers. Multiple cytotoxic chemotherapeutics have demonstrated activity. Most notable among these are dacarbazine (DTIC), temozolomide, and platinum-based regimens, which yield response rates from 7% to 12%. Novel combinations of IL-2 and cytotoxic chemotherapy are also commonly employed; however, to date, such approaches have not been shown to be superior to standard salvage therapies. Because of the relatively poor response rates to cytotoxic agents, in recent years much emphasis has been placed on using small molecule inhibitors, or biologic agents targeting well-characterized genetic mutations in melanomas. The best characterized melanoma mutations for which there are biologic inhibitors are B-Raf, c-Kit and CTLA-4 (141).

Overall survival rates in women with vulvar melanoma are approximately 50% (142,143). Patients with superficial lesions have an excellent chance for cure after surgical resection, but patients with deeper lesions or metastases at the time of diagnosis have a more limited prognosis. These patients are good candidates for investigational trials.

Verrucous Carcinoma

Verrucous carcinomas are locally invasive and rarely metastasize (144). Consequently, treatment by radical wide excision is usually curative (145). Local recurrence can occur, especially when the tumor has been inadequately resected.

Basal Cell Carcinoma

Basal cell carcinomas should be removed by excisional biopsy using a minimum surgical margin of 1 cm (146). Lymphatic or distant spread is exceedingly rare (147). Local recurrence may

occur, particularly in tumors removed with suboptimal resection margins.

Adenocarcinoma

Patients presenting with vulvar adenocarcinoma should first undergo an extensive clinical evaluation to determine whether the lesion in question represents a primary versus metastatic tumor. Despite the paucity of data regarding the evaluation and treatment of vulvar adenocarcinoma, resection of localized disease by radical wide excision, hemivulvectomy, or radical vulvectomy seems appropriate (148). The incidence of groin node metastases is approximately 30% (149). Some form of inguinal lymphadenectomy should be included with primary surgical resection. Radiation therapy may have a role in enhancing local control for women with large primary tumors or inguinal metastases. The effectiveness of chemotherapy is unknown, although a single case report documents a response with pegylated liposomal doxorubicin in adenocarcinoma of the vulva (150).

Paget's Disease

Paget's disease is associated with an underlying invasive adenocarcinoma component in approximately 15% of cases (151). As many as 20% to 30% of patients will have or will later develop an adenocarcinoma at another nonvulvar location (152), although more recent series suggest a lower incidence of secondary malignancies (153). Observed sites of nonvulvar malignancies developing in patients with extramammary Paget's disease include breast, lung, colorectum, gastric, pancreas, and upper female genital tract. Screening and surveillance for tumors at these sites should be considered in patients with Paget's disease.

Paget's disease should be resected with a wide margin. If underlying invasion is suspected, the deep margins should be extended to the perineal fascia. Some suggest careful assessment of the surgical margins using multiple frozen sections to ensure complete excision (154,155). This approach can be cumbersome and may not influence the long-term incidence of recurrence. Pierie et al. showed that patients with microscopically positive margins had a significantly higher rate of recurrence; however, with extended follow-up, all patients eventually recurred (154). Others have shown that despite surgical efforts to the contrary, microscopically positive margins are frequent, and disease recurrence is common regardless of margin status (156). Repeat local excision of recurrent disease is usually effective in the absence of invasion (157).

Nonsurgical Therapy

Imiquimod is an immune modulator that is believed to affect the function of the Toll-like receptor (TLR) as a costimulatory molecule for T-cell-mediated immune response to malignant cells. It has well-documented activity for treatment of genital warts as well as vulvar dysplasia. It also reportedly has activity in extramammary Paget's disease. In several small case series, complete response (CR) rates of as much as 92% have been reported (158,159,160).

Vulvar Sarcomas

The specific histologic types are described in the pathology section of this chapter. All types of vulvar sarcoma are rare, but leiomyosarcoma, MFH, and rhabdomyosarcoma predominate (161,162). Cures have occasionally been obtained with aggressive resection of either primary or locally recurrent disease. The results of regional and systemic therapy for leiomyosarcoma are disappointing. These patients are excellent candidates for

FIGURE 19.14. Multiple in-transit lymphatic metastases from a cloacogenic carcinoma of the rectum. A large constricting lesion was evident on rectal examination.

clinical trials. Rhabdomyosarcoma seems to be more responsive to both chemotherapy and radiation. The current treatment of choice is to combine chemoradiation with limited surgical resection of residual disease (162,163).

Metastatic Tumors to the Vulva

Treatment of secondary vulvar tumors should be directed against the primary tumor. As with bulky vulvar cancers, a multimodal approach seems to provide some opportunity for long-term survival, along with enhanced local tumor control and organ preservation.

Cutaneous vulvar lymphatic metastases may occur as in transit tumor emboli from anorectal tumors or as retrograde flow metastases when bulky tumors of the cervix or uterus obstruct the normal lymphatic drainage patterns (Fig. 19.14). These metastases are multiple and are often bilateral. Their histology reflects that of the primary tumor. Because this metastatic pattern is associated with advanced tumors, the primary tumor should be readily detectable by examination.

SURGICAL TECHNIQUES

Wide Radical Excision

Several names have been applied to the procedures used to resect small vulvar cancers: partial deep excision, radical wide excision, radical local excision, wide local excision, modified radical vulvectomy, and hemivulvectomy. Regardless of the preferred nomenclature, the surgical procedure should be adequately defined and described. Surgical incisions are devised to allow for at least a 1 to 2 cm resection margin encompassing

FIGURE 19.15. This is a picture of an early vulvar cancer identified in a background of VIN III. A planned 2-cm margin is outlined.

the primary lesion (Fig. 19.15). Dissection is carried to the deep perineal fascia. Tumors located close to the anus or anal sphincter can be managed by radical wide excision with sphincter or flap repair, or they can be treated with combined modality therapy as outlined under the radiation therapy section. Most wide radical excision sites can be closed primarily. In some patients, fasciocutaneous pedicle flaps can be used to facilitate coverage of the vulvar defect. Some form of inguinal lymphadenectomy, performed through a separate incision, is generally combined with radical wide excision.

Ambulation is begun on the day of surgery. Perineal irrigation and air (natural or forced) drying is started within 24 hours of the surgery. The average hospital stay for patients undergoing radical wide excision is usually 1 to 2 days. Wound breakdown, usually of minor degree, is reported in at least 15% of cases (49,108). The incidence and severity of groin complications is proportional to the extent of the lymphadenectomy.

Inguinofemoral Lymphadenectomy

Appropriate surgical management of the groin nodes has been evolving for many years. Original descriptions of radical vulvectomy included *en bloc* resection of the vulva with inguinal and pelvic lymph nodes. The extent of lymphadenectomy was steadily reduced, first eliminating the pelvic node dissection and then reducing the extent of the groin dissection. The concept of superficial inguinal lymph adenectomy was proposed in the late 1970s; however, this approach was ultimately rejected by gynecologic oncologists due to an unexpectedly high relapse rate (Table 19.5).

Table 19.5 Unanticipated Groin Failure in Patients with Negative Superficial Lymphadenectomy

Investigators	No.	%
Burke et al. (165)	4/76	5.2
Berman et al. (65)	0/50	0
Stehman et al. (166)	6/121	5.0
Gordinier et al. (170)	9/104	8.6
Total	19/351	5.4

The most common current approach starts with an incision parallel and just above or below the inguinal ligament. The incision is carried through Campers fascia and small flaps are elevated to expose the lymph node-bearing fat and preserve blood supply to the skin. There is no need to skeletonize the femoral artery; however, identification of the medial wall of the femoral vein helps assure removal of the medial fat pad, where the SLN is frequently found. The dissection can usually be performed solely with electrocautery or a small vessel-sealing device. The saphenous vein is encountered at the lower medial margin of the dissection, and whenever possible should be preserved to reduce the risk for postoperative lymphedema. The dissected specimen is forwarded for pathologic assessment. The skin incision can be closed with either staples or absorbable sutures. A closed-suction drain is placed and removed when output is <25 mL per day.

Cadaver studies identify 8 to 10 lymph nodes in the femoral triangle defined by the inguinal ligament, sartorius muscle, and adductor longus. Surgical node counts are dependent on the thoroughness of the surgeon and pathologist.

The nomenclature of groin lymph nodes is inconsistent and confusing. The authors find the terms “deep” and “superficial” especially troubling and, in the SLN era, largely meaningless. A satisfactory groin dissection has been performed when the inguinal ligament, adductor longus, saphenous vein, medial wall of the femoral vein, and the fossa ovalis have been identified.

Sentinel Lymph Node Biopsy Technique

As discussed previously, SLNB should be offered as an alternative to inguinofemoral lymphadenectomy as part of the primary management in women with tumors ≤ 4 cm with no suspicious lymph nodes on physical examination or imaging and no prior groin surgery or radiation that might interfere with lymphatic drainage pathways. The authors obtain an LSG in most patients. If possible, the surgeon should perform the injection for vulvar cancer or assure that the nuclear medicine specialist is comfortable with injecting the vulva. The injection is painful and EMLA cream can be helpful. The half-life of the radiocolloid is approximately 6 hours, so a patient can be injected in the morning and then operated on the same day. Frequently this is not possible and a second radiocolloid injection will be necessary in the operating room. The blue dye is visible in the SLN for as little as 45 minutes. The authors typically inject the radiocolloid prior to sterile prepping and draping and inject the blue dye only when the team is prepared to make an incision. All injections are intradermal, 0.5 to 1.0 cm from the tumor itself. Intratumoral or subcutaneous injections will most likely result in a failure to identify the SLN.

Transdermal localization of the SLN using a handheld gamma counter is possible in most patients. SPECT/CT is also valuable for locating the SLN in relation to the femoral vessels (Fig. 19.16). A small incision is made over the location of the SLN. Although data are limited, clinical experience indicates the SLN is commonly medial to the femoral vein and just above the adductor longus muscle. Once the SLN is removed, the wound is scanned for any residual radioactivity. It is imperative that all SLNs in the groin are removed. The gamma counter may detect second echelon nodes in the pelvis just above the inguinal ligament. If blue lymphatic channels lead to a node that is not hot or blue it is still considered an SLN.

Within the pathology laboratory, the evaluation of SLNs requires detailed and systematic evaluation of the submitted specimen. The lymph node sample submitted requires proper identification of patient name, source, name of the surgeon submitting, node location, date, and number of nodes identified.

In sectioning SLNs, it is recognized that to achieve close to 100% identification of all metastases the section spacing needs to be one-half the diameter of the tumor to be detected

FIGURE 19.16 SPECT/CT demonstrating left sentinel lymph node just medial to femoral vein. SPECT/CT provides superior localization of sentinel lymph nodes compared with 2-dimensional lymphoscintigraphy. The number of sentinel nodes identified should correspond to the number removed at surgery.

(162). The lymph node or nodes are sliced in 1 to 2 mm slices, cutting the lymph node at right angles to the long axis of the node. All of the lymph node tissue (slices) should be submitted for study.

Once the nodal tissue is embedded in the paraffin block, the node slices can be cut at closer intervals to improve tumor detection. Although there are some variations on this sectioning method, our approach is to cut 3 sections from each block. After facing the block to get a full face of the sectioned nodal tissue, the first 5-micron section is cut. This section will be stained with hematoxylin and eosin (H&E). We then cut 100 microns into the block and cut another 5- μ m section. This second slide is held for additional H&E staining, or immunohistochemistry, if the first and last H&E sections have equivocal findings. We then cut an additional 100 microns into the block and take the third section. This slide is stained with H&E. The pathologist reviews the 2 H&E slides, and if the findings are equivocal, the held second slide is then studied.

Limited information is available regarding ideal surveillance following SLNB. Our preferred technique is ultrasound, since it is noninvasive and the internal architecture of the lymph nodes can be imaged (Fig. 19.17A, B). Early detection of a groin failure may help in improving outcomes with multimodality treatment.

Surgical Resection for Recurrent Disease

The site, extent, and volume of recurrent vulvar lesions dictate both resectability and potential for cure. Recurrences can be categorized as local (vulvar), inguinal, or distant (pelvis, lower extremity, or beyond). Surgical therapy plays a curative or palliative role in selected subsets of patients with recurrent disease.

Wide Radical Excision

As many as 75% of patients with recurrent disease limited to the vulva can be salvaged by radical wide excision (partial deep vulvectomy) or reexcision of the tumor (133,134). Surgical principles of recurrent vulvar tumors are identical to those for primary tumors: wide excision with a measured normal tissue margin of at least 1 to 2 cm. Particular attention is also focused on obtaining a clear deep margin. Because most patients have had prior operative therapy, primary closure of the vulvar defect is frequently more difficult. More complex reconstructive efforts may be needed to restore tissue integrity.

FIGURE 19.17 **A** and **B**: Close surveillance following sentinel lymph node biopsy is recommended since groin relapse is difficult to treat. Physical examination is very unreliable. Ultrasound can be very effective, as illustrated here. Six months after negative sentinel lymph node biopsy, ultrasound detected a 5-mm metastasis. Fine needle aspiration confirmed metastatic disease. The patient underwent inguinal femoral lymphadenectomy and radiation therapy. She remains disease-free at 2 years.

Radical Vulvectomy

In very rare circumstances, radical vulvectomy may be indicated for recurrent vulvar cancer. The classic description of radical vulvectomy and bilateral lymphadenectomy can be described as based on either a “butterfly” or “longhorn” approach. The butterfly incisions use convex “wings” over the groin and around the anus to facilitate closure of the defect (Fig. 19.18). The longhorn incisions were developed to limit skin resection over the groin in an attempt to reduce wound breakdown (164). The arcing superior incision is placed from the lateral margins of the groin dissection across the mons pubis. The lateral vulvar incisions are placed at the labiocrural folds, because these topographical landmarks represent the most lateral location of the superficial vulvar lymphatics. The perianal incision is placed to allow resection of the perineal body. These incisions are taken to the level of the deep inguinal and perineal fascia and permit *en bloc* removal of both superficial and deep groin nodes, the entire vulva, and an intervening skin bridge.

After removal of the specimen, the skin and mucosal edges are undermined to permit mobilization and primary closure with delayed absorbable suture. Some degree of tension at the suture lines is unavoidable, particularly in the perineal body and periurethral areas. Closed suction drains are usually placed in the groin sites to remove excess lymphatic- and serous-fluid accumulations and are usually removed when drain output is minimal (5 to 14 days).

FIGURE 19.18: Butterfly incision described for a traditional radical vulvectomy with bilateral inguinal lymphadenectomy. Modern indications for radical vulvectomy are exceedingly rare. The patient shown in Figure 19.5 was treated with concurrent chemoradiation and still had bilateral gross tumor. This figure demonstrates the field following resection.

Some degree of wound breakdown is seen in approximately 50% of patients. Local wound care results in satisfactory secondary healing in most of these cases. Lymphocyst formation is relatively common and frequently presents as a tense but nontender groin mass. Percutaneous needle drainage is usually sufficient, but occasionally replacement of a groin drain may be required. Inguinal cellulitis, lower extremity lymphangitis, and lymphedema are uncommon late sequelae. The incidence of these complications is related to the extent of groin therapy and is highest in patients treated with superficial and deep lymphadenectomy along with groin irradiation. The 3-incision concept preserves the radicality of the vulvar resection while retaining skin over the groin. Consequently, the incidence of major wound breakdown is significantly reduced to approximately 15% to 20% of cases (165,166,167). As with other techniques, the incidence and severity of groin complications such as infection, wound breakdown, or lymphocyst formation is still high (168). There are few if any indications for radical vulvectomy as the primary treatment for vulvar cancer.

Pelvic Exenteration

Curative resection may still be possible when vulvar recurrence extends to the vagina, proximal urethra, or anus. Selected patients have achieved long-term survival after pelvic exenteration for such recurrences (169,170). The surgical approach in these cases should be individualized to the size and location of the recurrent tumor, prior therapies, and the age and overall health of the patient. Patients considered for pelvic exenteration should have a thorough preoperative evaluation to exclude the presence of regional and/or distant metastases. Frequently, anterior or posterior exenteration with an extended vulvar phase will provide excellent resection margins while allowing preservation of either urinary or fecal continence. The techniques used to perform the exenteration are identical to those routinely used for the treatment of women with recurrent cervical carcinoma. Multiple vulvar and perineal reconstructive techniques have been described for coverage of large surgical defects (171,172,173,174).

Resection of Groin Recurrence

Patients who develop isolated groin recurrence should be treated with multimodality treatment if radiotherapy is still an option. Surgical resection should be viewed with caution in the

previously irradiated patient. A resection with negative margins usually requires the resection of vessels or bone with plastic reconstruction. Ultraradical surgery attempted in young patients with outstanding performance status and a small relapse in an irradiated groin that appears resectable on preoperative imaging is associated with high morbidity. Extended survival is possible for the few patients who achieve control of recurrent disease in the groin and do not later manifest distant metastasis (175). Isolated groin recurrence is a rare event, so the data to support the efficacy of this treatment are anecdotal.

Vulvar Reconstruction

With careful planning and adequate tissue mobilization, most vulvar defects can be closed primarily. When large portions of the vulva have been resected, when tissue mobility is poor, or when radiation therapy has been administered previously, primary closure may not be feasible. Alternate tissue sources must be considered for these difficult cases. Categorically, the 2 types of techniques commonly employed for extensive vulvar reconstruction are fasciocutaneous flaps and myocutaneous flaps. Both categories of flaps have been well described as hearty and aesthetic options for patients who need a large tumor resected; however, the techniques referenced below should only be employed by surgeons who are regularly practiced in their use. Our practice routinely consults plastic surgery for patients in whom a complicated closure will be likely.

Fasciocutaneous Advancement Flaps

There are a number of different fasciocutaneous advancement flaps described for vulvar reconstruction. Nearly all of them are based on the rich, redundant blood supply from the internal pudendal artery and subsequent superficial perineal artery perforators that approach the vulva and perineum primarily from the posterior and lateral directions. The significance of this is that most vulvar fasciocutaneous flaps are designed with the intent to preserve fasciocutaneous perforators from these directions.

The most widely utilized pedicle flap among gynecologic oncologists has been the rhomboid flap; however, lotus pedicle flaps have also become more commonly used by plastic surgeons for closure of large vulvar defects. While detailed discussion of the techniques employed for these flaps is outside the intended scope of this chapter, references for multiple fasciocutaneous flaps that have been employed by these authors are referenced here (171–173,176).

Myocutaneous Flaps

Myocutaneous flaps, in comparison to fasciocutaneous advancement flaps, include a segment of muscle and usually receive their blood supply and innervation through an identifiable, named neurovascular pedicle. These are usually large, thick tissue sources that are best suited for the reconstruction of substantial defects. Each of the following listed flaps has notable advantages and disadvantage. Several types of myocutaneous flaps, namely the gracilis, gluteus maximus, tensor fascia lata, vastus lateralis, and vertical rectus abdominus flaps have been used to provide repair and reconstruction of large vulvar and groin defects (177). Historically, the gracilis flap was used to fill large vulvar and urogenital defects; however, in recent decades, the myocutaneous flap most commonly described for extensive vulvar reconstruction is the vertical rectus abdominus flap, which is based on the robust inferior epigastric pedicle. As with fasciocutaneous flaps, a detailed description of each flap is beyond the intended scope of this chapter; however, a number of techniques are referenced here (176–179).

RADIATION THERAPY

Early accounts of severe skin peeling and poor survival rates after primary radiation treatment of vulvar carcinomas led some investigators to surmise that radiotherapy had a narrow therapeutic role in the curative management of patients with vulvar cancer (180,181). The use of high doses of radiation alone, delivered with low-energy ⁶⁰cobalt photons and *en face* electron boosts, in patients who were mostly poor surgical candidates, resulted in a suboptimal therapeutic benefit between tumor control probability and normal tissue complications (182). More modern-day practices, such as incorporating consecutive daily fractionation, attention to dosimetric planning detail, and appreciation of vulvar and low pelvic radiation tissue tolerance limits, have undoubtedly shown that relatively high doses of irradiation can be delivered safely. In selected patients, treatment of the vulva and/or regional lymph nodes by fractionated radiation improves locoregional control rates and survival rates, and may even reduce overall treatment morbidity. Radiation therapy is now accepted as an important element in the multidisciplinary management of patients with advanced vulvar cancer involving the pelvis and groin.

Treating Locally Advanced Disease in the Vulva

Following initial resection of a vulvar primary tumor, various surgicopathologic features have been identified that are associated with a higher risk of local recurrence. Podratz et al. reported a 24% incidence of vulvar recurrence in 71 patients with stage III carcinoma (183). Recurrence was correlated with tumor size and nodal status. Heaps et al. reported that a close surgical margin was the most powerful predictor of local recurrence in their patients (97). They observed 21 vulvar recurrences in 44 patients with tumor margins <8 mm (deep or at the skin surface), compared with no local recurrences in 91 patients with margins ≥8 mm (after fixation). The importance of a pathologic margin distance ≥8 mm in optimizing local vulvar control and 5-year disease-specific survival has also been emphasized in a recent analysis by Chan et al. (98). Lymphovascular space invasion and deep tumor penetration are also associated with a greater and increased risk of recurrence (97,184,185). Although many local recurrences are controlled with additional surgery or irradiation, salvage surgery is often morbid, and local recurrences may provide additional opportunity for regional and distant tumor spread. While no prospective trials of postoperative vulvar site radiotherapy have been completed, adjuvant radiation of the primary tumor bed in selected patients with close margins or other high-risk features does improve vulvar tumor control (186).

Alternatively, in patients who present with more advanced primary tumors, radiation therapy may be delivered preoperatively. Advocates of this approach have listed several theoretical advantages for patients with locally advanced vulvar carcinomas:

1. Less radical resection of the vulva may be adequate to achieve local tumor control after preoperative treatment of the vulva with radiation;
2. Tumor regression during radiation may allow the surgeon to obtain adequate tumor-free surgical margins without sacrificing important pelvic structures such as the urethra, anus, and the clitoris; and
3. Radiation treatment alone may be sufficient to sterilize microscopic regional disease when the inguinal nodes are clinically normal and may mobilize fixed and matted nodes, facilitating subsequent surgical excision.

Table 19.6 Concurrent Chemoirradiation in the Management of Locally Advanced or Recurrent Carcinoma of the Vulva

Investigators	No. of Patients	Chemotherapy	RT Dose (Gy)	No. with Recurrent or Persistent Local Disease after RT Surgery	Follow-up (months)
Moore et al. (2012)	58	CDDP	57.6	21 (36%)	24.8
Moore et al. (154)	73	5-FU + CDDP	47.6	15 (21%)	22–72
Gerszten et al. (249)	18	5-FU + CDDP	44.6	3 (17%)	1–55
Cunningham et al. (234)	14	5-FU + CDDP	45–50	4 (29%)	7–81
Landoni et al. (240)	58	5-FU + Mito	54	13 (22%)	4–48
Akl et al. (246)	12	5-FU + Mito	30–36	0	8–125
Han et al. (247)	14	5-FU + CDDP or Mito	40–62	6 (43%)	4–273

Note: 5-FU, 5-fluorouracil; CDDP, cisplatin; Mito, mitomycin C; RT, radiation therapy.

Although the published experiences with preoperative single-modality radiation therapy are small, several investigators have reported excellent responses and high local control rates after treatment of advanced tumors with relatively modest doses of radiation therapy followed by local resection (187,188). These reports provided emerging evidence that radiation could significantly debulk advanced local disease and allow for more conservative, viscera-sparing surgery while preserving good local control.

Data have emerged supporting the therapeutic benefit of radiochemotherapy, typically followed by limited surgical resection, in addressing locally advanced disease (Table 19.6) (115,189,190). These trials were initially prompted by extrapolation from superior local control and survival outcomes after radiochemotherapy for anal cancer (189,190). Typical regimens have included combinations of radiation coadministered with 5-fluorouracil (5-FU), and cisplatin or mitomycin C. Most investigators have observed remarkable regressions of bulky lesions with radiochemotherapy, suggesting that therapeutic responses may be better than would be expected with radiation alone. Randomized trials of the role of radiochemotherapy have not been done and are unlikely to be feasible within this disease, given the small number of patients and heterogeneity of clinical presentation. However, recent single experimental arm trials have demonstrated improved local control and survival when concurrent cisplatin chemotherapy was added to radiation in locally advanced vulvar cancers (191,192).

The most compelling data in support of concurrent radiochemotherapy in the management of locally advanced disease come from 2 large prospective phase 2 trials performed by the Gynecologic Oncologic Group (GOG protocols 101 and 205). In the first study (GOG protocol 101), 71 evaluable patients with locally advanced T3 or T4 disease who were deemed not resectable by standard radical vulvectomy underwent preoperative radiochemotherapy. Chemotherapy consisted of 2 cycles of 5-FU and cisplatin. Radiation was delivered to a dose of 47.6 Gy, using a planned split-course regimen, with part of the radiation given twice daily during the 5-FU infusion. Patients underwent planned resection of the residual vulvar tumor, or incisional biopsy of the original tumor site in the case of complete clinical response, 4 to 8 weeks after chemoradiotherapy. A complete clinical tumor response was noted in 33 of 71 patients (47%). Following vulvar excision or biopsy, 22 patients (31%) were found to have no residual tumor in the pathologic specimen. In all, only 2 of 71 patients (3%) had unresectable disease after radiochemotherapy, and in only 3 patients was it impossible to preserve urinary and/or gastrointestinal continuity following complete resection of the primary tumor residuum. With a median follow-up interval of 50 months, 11 patients (16%) have developed locally recurrent

disease in the vulva (115). These results are all the more notable considering the relatively low dose of radiation used in these typically bulky, advanced tumors. Building on this experience, investigators sought to study weekly cisplatin chemotherapy coadministered with radiation (GOG protocol 205). On this trial, 58 evaluable patients with untreated locally advanced T3 or T4 disease not amenable to standard radical vulvectomy underwent preoperative radiochemotherapy (196). On this contemporary study, radiation totaled 57.6 Gy in 32 uninterrupted daily fractions of 1.8 Gy. Cisplatin (40 mg/m²) chemotherapy was administered weekly. Following vulvar excision or biopsy, 37 (64%) of 58 patients had no residual tumor in the pathologic specimen.

It is important to be cautious in designing aggressive treatment protocols for this group of patients, who are often elderly and have coexistent medical problems. Serious pulmonary toxicity has been observed in patients treated with bleomycin (193,194). In the largest published series of patients treated with mitomycin C and 5-FU, hematologic tolerance was acceptable, but the administered dose of mitomycin C was more conservative than is usually used in the treatment of anal cancers (195). Other investigators have confirmed the increased toxicity associated with concurrent radiochemotherapy, especially with the use of mitomycin C–based regimens (196).

Following radiochemotherapy for locally advanced disease, it remains undefined whether surgery is necessary in those who achieve complete clinical response. In GOG 101, approximately 70% of patients who achieved complete clinical response were found to have no pathologic residual in the surgical specimen. In GOG 205, 34 of 37 patients (92%) underwent surgical biopsy only to assess radiochemotherapeutic response. Of these 34 women, 29 (78%) had biopsies showing a complete response to radiochemotherapy. At this point, we continue to recommend biopsies of the original tumor bed in patients who achieve complete clinical response. In those with residual vulvar disease after radiochemotherapy, surgical resection would be individualized and tailored to the extent and location of residuum.

Treatment of Regional Disease

Although radical inguinal lymphadenectomy has historically been considered the treatment of choice for regional management of invasive vulvar carcinoma, a number of retrospective studies have suggested that regional prophylactic radiation therapy is an effective method of preventing groin recurrences with minimal morbidity (197,198). In a large single-institution retrospective analysis, Katz et al. reported no differences in the

inguinal relapse rates for patients treated with prophylactic groin irradiation compared with those undergoing lymph node dissection (195). Leiserowitz et al. observed no groin recurrences in 23 patients with locally advanced, clinically N0 vulvar cancers after prophylactic treatment of the groin with concurrent radiochemotherapy (198).

The GOG tried to define the optimal approach to clinically negative inguinal nodes in a trial that randomized patients between inguinal node irradiation and radical lymphadenectomy (followed by inguinopelvic radiation in patients with positive nodes) after resection of the primary tumor (199). This study was closed after entry of only 58 patients when there appeared to be a higher rate of groin recurrence in the radiation treatment arm. However, this study has been criticized because the treatment protocol was not CT-based, it recommended combination photon and electron dosing to a depth of 3 to 4 cm, and likely delivered an inadequate dose to the inguinal nodes (200,201).

While the role of prophylactic radiotherapy in the undissected but high-risk groin remains controversial, there is strong evidence that adjunctive radiation therapy improves regional tumor control and survival in patients who have documented nodal metastases following inguinal node dissection. Retrospective studies suggested that patients with metastases to multiple nodes or extranodal tumor extension had an increased risk of groin recurrence after radical surgery and therefore may benefit from radiation therapy (202,203). However, the critical role of radiation therapy was not appreciated until 1986, when Homesley et al. published results of a prospective GOG trial in 114 patients with inguinal metastases (131). In that study, all patients underwent radical vulvectomy and inguinal lymphadenectomy. Patients who had positive inguinal nodes were randomized intraoperatively to receive either pelvic node dissection or postoperative irradiation to the pelvis and inguinal nodes. This trial was closed before the projected accrual goal because an interim analysis revealed a statistically significant overall survival advantage for the radiation treatment arm ($p = 0.03$). The differences between the 2-year survival rates of patients treated with radiation therapy or pelvic dissection were most marked for patients presenting with clinically positive nodes (59% and 31%, respectively) and for those with 2 or more positive groin nodes (63% and 37%, respectively). Extended follow-up showed a narrow, nonsignificant 6-year overall survival rate (51% after radiation versus 41% after pelvic dissection) (132). Yet, the cancer-related death rate was significantly higher for pelvic node resection than for radiation (hazard ratio, 0.49 [95% CI, 0.28–0.87]; 51% versus 29% at 6 years, respectively) (132). Moreover, there was no significant difference in survival between the treatment groups for patients with only one microscopically positive node, although the authors commented that the number of patients in this subset was insufficient for reliable analysis. After long-term follow-up of patients on this study, those patients with one microscopically positive node had no survival benefit after radiation (132). The most striking difference in the patterns of recurrence for the 2 treatment groups was the much larger number of inguinal failures among patients who were treated with surgery alone (Fig. 19.19). These groin recurrences were rarely if ever salvageable. The vulva, regardless of tumor pathologic risk factors, was not included in the radiation treatment fields in this study, and approximately 8% of patients in both treatment arms had recurrences at the primary site at the time of the analysis, raising the question of whether selective radiation to the vulva may have decreased local recurrences. It is important to recall that while subset analysis showed the most dramatic benefit of adjuvant radiotherapy for clinically positive adenopathy or 2 or more pathologically involved nodes (131,204), the trial was closed early because of an overall survival benefit before subset analysis. The role of adjuvant radiation for patients with a single positive groin node following inguinal node dissection remains unresolved (132). Retrospective reviews of patients with only a

FIGURE 19.19. Sites of disease recurrence in patients treated with adjuvant radiation therapy to the pelvis and inguinal region or with pelvic node dissection following radical vulvectomy and bilateral inguinal lymphadenectomy. Source: Modified from Homesley HD, Bundy BN, Sedlis A, et al. Radiation therapy versus pelvic node resection for carcinoma of the vulva with positive groin nodes. *Obstet Gynecol.* 1986;68:733–740.

single positive inguinal nodal metastasis from vulvar cancer suggests that adjuvant radiation may provide therapeutic benefit if the groin node dissection was less extensive in scope or if a ratio of more than 20% positive ipsilateral groin nodes (number positive/number resected) was found at the time of surgery (132,205). Another indication that radiation may be useful in the single positive inguinal lymph node patient is derived from data in the GROningen International Study on Sentinel nodes in Vulva cancer (GROINSS-V) study (206). Patients with a single sentinel node metastasis larger than 2 mm had a lower disease-specific survival (69.5%) than those patients with a single sentinel node metastasis 2 mm or smaller (94.4%, $p = 0.001$).

The role of preoperative radiochemotherapy has been assessed in patients who present with bulky, unresectable inguinal adenopathy. In the GOG 101 study of preoperative radiochemotherapy for local regionally advanced vulvar cancer, there was a cohort of 42 evaluable patients with N2 or N3 nodal disease who were deemed initially unresectable. Patients received 47.6 Gy of radiotherapy in split-course fashion, with 2 concurrent cycles of 5-FU and cisplatin, as described above. Three to 8 weeks later, planned inguinofemoral lymph node dissection was performed. In only 2 patients (5%) did nodal disease remain unresectable. The surgical specimen showed histologic clearance of nodal disease in 15 patients (36%). At a median follow-up of 78 months, only 1 of 37 patients (3%) who completed the full prescribed regimen of preoperative radiochemotherapy and bilateral inguinofemoral node dissection relapsed in the groin (207). This study, while nonrandomized, provides further evidence of the efficacy of combined chemoradiotherapy in the management of local regionally advanced vulvar cancer and of patients with significant regional adenopathy. Given the high risk of distant relapse with node-positive vulvar cancer, especially in those with ≥ 2 involved nodes (132), it seems reasonable to consider adjuvant radiochemotherapy for such high-risk patients, provided that careful attention is paid to treatment planning and amelioration of toxicity. Results from GOG 205 echo these sentiments (189).

Radiation Therapy Technique

Radiation techniques used for treatment of vulvar carcinoma reflect a need to cover the vulva plus lower pelvic and inguinal nodes, while simultaneously minimizing radiation dose to the femoral heads. One approach is to treat with an anterior field that encompasses the inguinal regions, lower pelvic nodes, and

FIGURE 19.20. The radiation dose to the femoral heads can be reduced by delivering part of the dose to inguinal nodes with appropriate-energy electron fields. In this example, a wide anterior 6-MV field encompasses the primary site as well as the inguinal and pelvic nodes. Electron fields are placed anteriorly to overlap slightly with the exit of a narrower posterior 18-MV field that encompasses the primary and pelvic nodes

vulva, and a narrower posterior field that encompasses the lower pelvic nodes and vulva but excludes the majority of the femoral heads (Fig. 19.20). The intent here is to cover one nodal echelon proximal to the nodal echelon with metastatic vulvar cancer disease. The inferior-most borders of the fields should extend to the saphenous vein. If the fields are evenly weighted to the mid-plane of the pelvis using 6 MV photons, the contribution of the anterior field to the groin nodes at a depth of 3 to 5 cm will generally be 60% to 70% of the dose to the mid pelvis. The difference may be made up by supplementing the dose to the lateral groins with anterior electron fields of appropriate energy (Fig. 19.20). Currently, CT scans obtained in the process of radiation dose planning are used to detect enlarged nodes that may not be appreciated on clinical exam and to determine the appropriate electron energy. Gross disease in the groin or vulva may be boosted with *en face* electron fields. In some cases, interstitial implants or *en face* electron fields may be used to boost the dose to the primary site. If radiation is directed to the regional nodes only, with intentional sparing of the

vulva, care must be taken to avoid a large “midline” block, which may lead to higher medial groin and vulvar failures.

The complex anatomy of the vulva and its regional lymphatics has led some investigators to propose the use of IMRT in the management of vulvar cancer (Fig. 19.21) (207). To whom IMRT should be offered remains debated. In modern practice, IMRT may replace conventional external beam approaches used in the treatment of vulvar cancer; however, outcome data remain limited. Most data comes from experience extrapolated from the treatment of anal carcinoma in multi-institutional clinical trials (208,209) or single academic cancer center studies in this disease (210,211). IMRT is gradually being used more for radiotherapeutic management of gynecologic malignancies, including vulvar cancer. IMRT is an attractive approach to radiotherapy in the pelvis because of its ability to escalate radiation dose while lower radiation dose to nearby healthy normal tissue, improving the therapeutic window for radiation. An initial study has shown dosimetric and clinical benefits, with reduction in gastrointestinal and hematopoietic toxicity (210). Consensus indications and guidelines for vulvar IMRT are being written.

Although radiobiologically effective, IMRT has a number of practical limitations that must be acknowledged. Uncertainties in patient set-up and target volume definition when using IMRT techniques have been raised. Physical travel limits of IMRT multileaf collimators may be exceeded when targeting primary site disease and bilateral groin node basins. When travel limits are exceeded, IMRT radiation portals may have to be cut into 2 or more collimator carriage movements. Additive scatter and leakage radiation dose to normal tissues may occur. Vulvar and groin target motion resulting from quiet breathing during treatment is expected to be minimal, as is shifting bladder and rectal volumes unlikely to substantially modify primary disease position during beam-on time. Again borrowing from overall radiotherapy experience, it is not unreasonable to conclude that daily repositioning of women prior to radiation delivery, using such devices as on-board cone beam CT, will adjust for set-up inconsistencies. For vulvar cancer management, IMRT remains under inspection and an active area of research in this disease.

Furthermore, robotic stereotactic body radiosurgery has been attempted in patients with recurrent disease after previous irradiation. Here, radiation is delivered using a linear accelerator mounted on an industrial robotic arm. By allowing “pencil-beam” noncoplanar radiation delivery, robotic stereotactic body

Vulvar cancer – locally advanced T4N2

FIGURE 19.21. Intensity modulated radiation therapy in the management of vulvar cancer.

radiosurgery delivers accurate and precise radiation (0.4 mm precision) at an escalated dose per fraction that is considered ablative (>8 Gy per fraction). In one report, 3 women underwent palliative stereotactic body radiosurgery (8 Gy × 3 fractions = 24 Gy) with complete regression of their bulky vulvar tumors (212). While the treatment was successful, inability to identify occult microscopic disease at the time of radiosurgical planning led to disease relapse outside and abutting the radiosurgical target in all 3 women. Incorporating advanced imaging, such as 2-[¹⁸F]fluoro-2-deoxy-D-glucose (¹⁸F-FDG) scans, improves target localization and is likely to improve the therapeutic usefulness of this approach (213).

Acute Complications of Radiation Therapy

Acute radiation reactions are brisk, and doses of 35 to 45 Gy routinely induce confluent moist desquamation. However, with adequate local care, this acute reaction usually heals within 3 to 4 weeks. Sitz baths, steroid cream, and treatment of possible superimposed *Candida* infection all help to minimize the discomfort. If the patient is sufficiently flexible, she may be placed in a frog-leg position during treatment to minimize the dose and ensuing skin reaction on the medial thighs; care must then be taken, however, to deliver an adequate dose to the vulvar skin. Although most patients will develop confluent mucositis by the fourth week of treatment, this is usually tolerated if the patient is warned in advance and assured that the discomfort will resolve after treatment is completed. Although a treatment break is occasionally required, delays should be minimized, because they may allow time for repopulation of tumor cells.

Late Complications of Radiation Therapy

Many factors add to the late morbidity of radiation treatment in patients with vulvar carcinoma. Patients with advanced vulvar carcinomas often are treated with radiation therapy following radical surgery, which may include extensive dissection of the inguinal and possibly pelvic nodes. Large ulcerative cutaneous lesions frequently have superimposed infection. Patients are often elderly and may have complicating medical conditions, such as diabetes, multiple prior surgeries, and osteoporosis. The contribution of concurrent chemotherapy to local morbidity is not yet clearly defined but may contribute to bowel and bone complications (208,209).

The incidence of lower extremity edema after inguinal irradiation alone is negligible (197,203). Radiation therapy is likely to contribute to the cumulative incidence of peripheral leg edema following radical node dissection, but there was no difference evident in the GOG randomized study of radiation (16%) versus pelvic node dissection (22%) (204). Femoral head fractures have occasionally been reported in patients treated with irradiation to the inguinal nodes (187,195). Techniques that limit the dose to

the femoral heads to less than 35 Gy should minimize the risk of this complication. It is not known whether severe osteoporosis contributes to femoral head complications. In general, with careful treatment planning techniques, the risk of major late complications following regional nodal radiation, either electively or adjuvant to lymph node dissection, is low (197). It has been suggested that concurrent chemotherapy may increase the risk, but this remains to be adequately substantiated (191,208).

The effect of radiation therapy on the long-term cosmesis and function of the vulva is poorly understood. Although treatment with radiation or radiochemotherapy and wide excision is becoming a more accepted alternative to extensive surgery for selected patients, and major complication rates appear to be acceptable, very little has been reported regarding more subtle late effects of such treatment in the vulva. Late effects are dose related. Better information will become available only as treating physicians record and report the late cosmetic and functional results of treatment (191,214).

CHEMOTHERAPY

Primary Treatment of Advanced Disease

The majority of patients diagnosed with vulvar cancer can be cured with surgery with or without postoperative radiation therapy; thus, chemotherapy monotherapy has traditionally been used solely for salvage therapy. Patients with advanced vulvar cancers tend to be older, with significant medical comorbidities, making them poor candidates for cytotoxic therapy because of concomitant diseases that increase the likelihood for significant adverse effects. Furthermore, recurrent vulvar cancer often occurs in the setting of extensive prior surgery and/or radiation therapy, making tolerance to cytotoxic therapy poor.

Squamous Cell Carcinoma

Cytotoxic Chemotherapy

Squamous carcinoma is the only histologic type of vulvar cancer for which there is significant data assessing the utility of cytotoxic chemotherapy in recurrent or advanced primary vulvar cancer not amenable to surgery or radiotherapy. A number of drugs have undergone phase 2 testing (Table 19.7) (215–218). Among these, only doxorubicin and bleomycin appear to have significant clinical activity. Cisplatin, a drug that has demonstrated broad activity in most gynecologic tumors (e.g., epithelial ovary, endometrial adenocarcinoma, and endometrial mixed mesodermal tumors and squamous carcinoma of the cervix), has notably little activity as monotherapy in vulvar and vaginal squamous tumors. Paclitaxel dosed at 175 mg/m² every 3 weeks

Cisplatin	100 mg IV day 6				

^aFive of 6 responses with no prior therapy; one of 16 responses in refractory disease.

^bNo patient with prior radiation therapy or chemotherapy; responses were the same for primary therapy and recurrences; 8 patients had resectable disease after chemotherapy.

was evaluated in the EORTC phase 2 trial 55985. Thirty-one patients with metastatic or locally advanced carcinoma of the vulva were treated, and 29 were assessable for response. Grade 3 or 4 toxicity was seen in 27.6% of patients, and objective responses were seen in just 13.8% of patients.

Several drug combinations have also been used in squamous vulvar cancer, most commonly as neoadjuvant therapy for patients with inoperable disease. Combinations used in vulvar squamous cancer are detailed in Table 19.8 (219,220).

Recognition of the fact that Epidermal Growth Factor Receptor (EGFR) expression via immunohistochemical staining is elevated in malignant vulvar tumors has led to the use of EGFR tyrosine kinase inhibitors (TKIs) as monotherapy and in combination with cytotoxic chemotherapy for use in palliation of advanced and recurrent vulvar cancer patients. Olawaiye in 2007 reported 2 dramatic partial responses to single agent erlotinib in women with advanced, treatment refractory disease; Bacha in 2010 reported a PR in a woman with advanced disease (221,222). A phase 2 GOG trial using erlotinib in advanced or recurrent vulvar cancer patients is under way.

RESULTS OF THERAPY

The overall results of therapy for women with squamous cancers of the vulva are excellent based largely on the fact that approximately two-thirds of patients present with early-stage tumors. Five-year survival rates for vulvar cancer have improved over the past 2 decades. Landrum et al. used GOG data to perform an historical comparison between patients treated between 1977 and 1984 ($n = 577$) with patients treated between 1990 and 2005 ($n = 175$). Stratification into “minimal, low, intermediate, and high” risk groups was performed to enable comparisons. Patients treated in the era of less radical surgery and modern chemoradiation fared better than historical comparisons, with 5-year survival by risk group (minimal → high) of 100% versus 97.9%, 97% versus 87.4%, 82% versus 74.8%, and 100% versus 29.0% (96).

Several strategies to enhance survival for women with vulvar cancer are evident. High-risk patients can be educated and screened more consistently for the development of early cancer.

Women with HPV infections, *in situ* vulvar disease, long smoking history, and other genital neoplasms are at risk for developing vulvar cancer. Careful screening targeted at women with these high-risk factors may lead to improvements in early diagnosis.

The survival rate for women with nodal spread is one-half that for women without nodal disease who have similarly sized primary tumors (Fig. 19.22). Improvements in the use of molecular markers for metastatic disease and biologic aggressiveness would be helpful for triaging higher risk patients into more effective adjuvant therapies. And, of course, there is a dire need for better treatment options for node-positive patients.

SEQUELAE OF TREATMENT

Immediate complications such as wound infection and lymphocyst were common in the radical vulvectomy era. These complications occur much less frequently due to less radical surgery and innovations such as prophylactic antibiotics and closed suction drains. Breakdown of the vulvar incision is increased in patients who are smokers, have vasculopathy, and display chronic poor hygiene.

Lymphedema starts to appear within weeks of surgery. The severity is related to the extent of groin surgery, wound complications, postoperative radiation therapy, and preexisting conditions of the lower extremities. Lymphedema is not limited to the lower leg and thigh. It may also include the mons, groins, and hips. The use of SLNB reduces but does not eliminate wound complications and lymphedema.

Pressure stockings, sequential compression devices, lymphedema massage, and microvascular surgery have been used to manage lower extremity lymphedema, with limited results. Prevention of lymphedema with the use of SLNB is the best strategy for limiting the adverse effects of this complication.

All gynecologic surgery, especially surgery for vulvar cancer, can have an adverse effect on body image and sexual function. Informed consent obtained for vulvar cancer surgery should include a discussion regarding these risks. No assumptions regarding a woman's sexual activity should be made based on age or marital status. We have found that preoperative consultation with a sexual health expert can be invaluable for many women.

FUTURE DIRECTIONS (RESEARCH, POTENTIAL MANAGEMENT CHANGES)

The incorporation of SLNB into the care of women with vulvar cancer raises many new questions regarding treatment of lymph node-positive patients. Should a woman with a microscopically positive SLN undergo full regional lymphadenectomy? How does the size of the metastasis impact the decision? Are isolated tumor cells clinically relevant? (223).

The GROINSVII/GOG 270 protocol, which is being conducted in Europe and North America, seeks to answer some of these questions. The original study design called for SLN-positive patients to be treated with 50-Gy radiation therapy to the groin. Early stopping rules were met because there was an unexpected number of patients with a groin relapse following SLNB and radiotherapy. On further analysis, there were no groin relapses among patients with metastases <2 mm. The study has been amended to require inguinofemoral lymphadenectomy for women with metastases over 2 mm and postoperative radiation therapy of 56 Gy. The role of adjuvant chemotherapy is unclear. GROINSVII/GOG 270 allows the use of concurrent cisplatin during radiotherapy, however, at the discretion of the treating physician.

Another area of interest will be targeted therapy. Phase 2 trials in vulvar cancer are unlikely; however, lessons learned from

squamous carcinomas of the anus or head and neck, as well as from cutaneous melanoma, may provide new options for patients with recurrent disease.

SUMMARY

Most patients with vulvar cancer are potentially curable at the time they present for care. The major challenge for providers is how to balance providing curative therapy with preserving quality of life, including organ function, sexual function, and body image.

The preferred therapy for patients with early disease is surgery alone. The morbidity of surgery can be reduced with the use of SLNB as an alternative to regional lymphadenectomy. This approach has proved very successful in the treatment of patients with breast cancer and cutaneous melanoma. There is now enough clinical evidence to support routine use in patients with vulvar cancer. Further investigation is needed to determine the ideal management of patients with a positive SLN.

Women with advanced disease usually benefit from multimodality therapy. The exact combination and order of treatment rely on consultation with a team including a gynecologic oncologist, radiation oncologist, pathologist, and diagnostic imager. Vulvar cancer is sufficiently infrequent that even busy clinicians should consider referral to a high-volume center when considering the care of women with vulvar cancer.

20 Vagina

HIGINIA R. CÁRDENES ■ JEANNE M. SCHILDER
■ ROBERT EMERSON

ANATOMY

The vagina is a muscular dilatable tubular structure averaging 7.5 cm in length that extends from the cervix to the vulva. It lies dorsal to the base of the bladder and urethra, and ventral to the rectum. The vagina forms from the upward spread of the epithelium from the urogenital sinus. The fused müllerian ducts meet the urogenital sinus at the müllerian tubercle. The hymen marks where the tubercle later opens up to establish the vaginal orifice. The upper portion of the posterior wall is separated from the rectum by a reflection of peritoneum, the pouch of Douglas. At its uppermost extent, the vaginal wall attaches to the uterine cervix at a higher point on the posterior wall than on the anterior wall. During embryonic development, there is no obvious demarcation between the portion of the fused müllerian ducts destined to form the uterus and those destined to form the upper vagina. In the later part of the third month of development, the uterine wall begins to be set off from the upper vagina at the cervical portion. A groove begins to form. This circular groove, formed at the juncture of the vagina and the cervix, is called the *forix*.

The vaginal wall is composed of 3 layers: the mucosa, muscularis, and adventitia. The inner mucosal layer is formed by a thick, nonkeratinizing, stratified squamous epithelium overlying a basement membrane containing many papillae. The epithelium normally contains no glands, but is lubricated by mucous secretions originating in the cervix. The epithelium changes little in response to the reproductive cycle. Beneath the mucosa lies a submucosal layer of elastin and a double muscularis layer, highly vascularized with a rich innervation and lymphatic drainage. The muscularis layer is composed of smooth muscle fibers, arranged circularly in the inner portion and longitudinally in the outer portion. A vaginal sphincter is formed by skeletal muscle at the introitus. The adventitia is a thin, outer connective tissue layer that merges with that of adjacent organs.

The proximal vagina is supplied by the vaginal artery branch from the uterine or cervical branch of the uterine artery. It runs along the lateral wall of the vagina and anastomoses with the inferior vesical and middle rectal arteries from the surrounding viscera (1). The accompanying venous plexus, running parallel to the arteries, ultimately drains into the internal iliac vein. The lumbar plexus and pudendal nerve, with branches from the sacral roots 2 to 4, provide innervation to the vaginal vault.

The lymphatic drainage of the vagina is complex, consisting of an extensive intercommunicating network. Fine lymphatic vessels coursing through the submucosa and muscularis coalesce into small trunks running laterally along the walls of the vagina. The lymphatics in the upper portion of the vagina drain primarily via the lymphatics of the cervix; the upper anterior vagina

drains along cervical channels to the interiliac and parametrial nodes; the posterior vagina drains into the inferior gluteal, presacral, and anorectal nodes. The distal vagina lymphatics follow drainage patterns of the vulva into the inguinal and femoral nodes and from there to the pelvic nodes. Lymphatic flow from lesions in the mid-vagina may drain either way (Figure 20.1) (2). However, because of the presence of intercommunicating lymphatics along the terminal branches of the vaginal artery and near the vaginal wall, the external iliac nodes are at high risk, even in lesions of the lower third of the vagina.

FIGURE 20.1. Lymphatic drainage of the vagina.

Source: Reprinted from Plentl AA, Friedman EA. Lymphatic system of the female genitalia. In: Plentl AA, Friedman EA, eds. *The Morphologic Basis of Oncologic Diagnosis and Therapy*. Philadelphia, PA:WB Saunders; 1971:55, Figure 5-2. Used with permission.

Such a complex lymphatic drainage pattern has significant implications for therapeutic planning. Therefore, bilateral pelvic nodes should be considered at risk in any invasive vaginal carcinoma, and bilateral groin nodes considered at risk in those lesions involving the distal third of the vagina. Although these drainage patterns serve as a general rule, recent data utilizing lymphatic mapping in women with vaginal cancer challenges the established drainage patterns (3). Frumovitz et al. found unexpected lymphatic drainage from primary lesions in the vagina, including 3 of 5 women with lesions located at the introitus that were found to have a sentinel node in the pelvis on pretreatment lymphoscintigraphy, when anatomic site would predict drainage to the inguinal triangle. Conversely, 2 of 4 women who had lesions in the upper third of the vagina were found to have a sentinel node in the inguinofoveal region when anatomic site would predict for involvement of pelvic lymph nodes.

EPIDEMIOLOGY AND RISK FACTORS

Primary vaginal cancer is a rare entity, representing only 1% to 2% of all female genital neoplasias. As cervical squamous cell carcinoma (SCC) is approximately 50 times more common than vaginal SCC, absence of concurrent cervical SCC or a history of cervical SCC within 5 years is usually considered a requirement for a tumor to be considered a vaginal primary, rather than involvement, or recurrence, of a cervical primary (54,55). Most vaginal neoplasms, 80% to 90%, represent metastasis from other primary gynecologic (cervix or vulva) and nongynecologic sites, involving the vagina by direct extension or lymphatic or hematogenous routes.

Creasman et al. (5) published the National Cancer Data Base (NCDB) report in 1998, based on 4,885 patients with primary diagnosis of vaginal cancer registered from 1985 to 1994. Approximately 92% of the patients were diagnosed with *in situ* or invasive SCC or adenocarcinomas, 4% with melanomas, 3% with sarcomas, and 1% with other or unspecified types of cancer. In the NCDB report, invasive carcinomas accounted for 72% of the carcinoma cases, or 66% of all vaginal cancers. *In situ* carcinomas accounted for 28% of invasive vaginal carcinomas, SCC represented 79%, and adenocarcinomas represented 14%. Adenocarcinomas represent nearly all the carcinomas in patients younger than 20 years of age and are seen less frequently with advanced age (5). In a more recent Surveillance, Epidemiology, and End Results program (SEER) study by Shah et al. (6), 2,149 women with primary vaginal cancer were diagnosed between 1990 and 2004. Squamous cell histology represented 65% of all cases, followed by adenocarcinomas 14%, melanoma 6%, and the other category representing the remaining 15% (6).

Carcinoma of the vagina is considered to be associated with advanced age, with the peak incidence occurring in the sixth and seventh decades of life. However, vaginal cancer is increasingly being seen in younger women, possibly due to human papillomavirus (HPV) infection or other sexually transmitted diseases. In the NCDB report, only 1% of the carcinoma patients were less than 20 years old at the time of diagnosis, and over 80% of those patients had *in situ* lesions. As patient age increased, the number of invasive tumors increased, reaching a peak in patients aged 70 to 79 years. The percentage of *in situ* carcinomas decreased to only 11% in patients over 80 years old (5). A decrease in the incidence of primary vaginal tumors has been noted in recent years, possibly because of early detection with cervical cytology or more rigid diagnostic criteria, which have eliminated from this category primary cancers arising from adjacent organs, such as the cervix, vulva, or endometrium.

Vaginal Intraepithelial Neoplasia and Squamous Cell Carcinoma

Potential risk factors for SCC include prior history of HPV infection, cervical intraepithelial neoplasia (CIN), vulvar intraepithelial neoplasia (VIN), immunosuppression, and possibly previous pelvic irradiation. HPV is the likely etiologic agent of SCC and its precursor lesion, vaginal intraepithelial neoplasia (VAIN). However, in contrast to cervical SCC, where almost all tumors contain detectable HPV-DNA, many vaginal SCCs are HPV negative. HPV has been detected in about 80% of VAIN lesions and 60% of invasive SCC of the vagina (7). In a case-control study of VAIN and early-stage cancer of the vagina, Brinton et al. (8) reported a 2.9-fold increase in therapy for genital warts and a 3.8-fold increase in prior abnormal Papanicolaou (Pap) smears in patients with VAIN compared to controls. The process most commonly occurs in the upper vagina, and it is frequently multifocal. Approximately one-half of the lesions are associated with concomitant CIN or VIN (9).

In studies reporting on groups of women with VAIN and SCC of the vagina, the following risk factors have been identified: 5 or more sexual partners, sexual debut before age 17 years, smoking, low socioeconomic status, a history of genital warts, prior abnormal cytology, and prior hysterectomy (7,8). Weiderpass et al., in a population-based study of 36,856 women, found that alcoholic women had an excess risk for cancer of the vagina, probably related to higher incidence of HPV infection associated with lifestyle factors such as promiscuity, smoking, use of contraceptive hormones, and dietary deficiencies (10). Iversen et al. (11) found no positive correlation between cancer of the penis in husbands and gynecologic cancer in their wives.

Patients with previous cervical carcinoma have a substantial risk of developing vaginal carcinoma, presumably because these sites share exposure and/or susceptibility to endogenous or exogenous carcinogenic stimuli. About 10% to 50% of patients with VAIN–carcinoma *in situ* (CIS) or invasive carcinoma of the vagina have undergone prior hysterectomy or radiotherapy (RT) for CIS or invasive carcinoma of the cervix (12–23). The interval from therapy for cervical cancer or preinvasive disease to the development of carcinoma of the vagina averages nearly 14 years, but there have been cases with the vaginal primary manifesting 50 years after therapy for cervical cancer (15,24).

It is controversial as to whether or not prior pelvic RT is a risk factor. Boice et al. (126) reported a 14-fold increased risk of cancer of the vagina in previously irradiated women before the age of 45 years, and a dose–response relationship was found to be significant. However, Lee et al. (25), in an analysis of 1,200 patients treated over a 20-year period at Washington University for carcinoma of the cervix, did not find prior RT to be associated with an increase in the incidence of pelvic second neoplasms. It is biologically plausible that there could be an apparent increase in risk given that prior pelvic RT would have likely been given for HPV-associated cervical carcinoma, and the antecedent HPV infection would increase the risk of SCC in the vagina. Such an association has led to the recommendation that patients treated for CIN or carcinoma of the cervix continue to undergo lifelong surveillance with vaginal cytological evaluation even after hysterectomy (26). In addition, Bornstein et al. (27) reported an incidence of CIN and VAIN after *in utero* exposure to diethylstilbestrol (DES) twice as high as in unexposed women. The putative mechanism is an enlargement of the transformation zone at risk, which is then at risk for infection with HPV (27).

Clear Cell Adenocarcinoma

Adenocarcinomas comprise approximately 14% of primary malignancies at this anatomic site (5,52). Primary adenocarcinomas

of the vagina may be associated with several presumed precursor lesions including adenosis, endometriosis, and mesonephric rests.

Clear cell adenocarcinoma (CCA) related to *in utero* DES continues to receive attention as the prototypical example of disease caused by an endocrine-disrupting chemical (61). The incidence of CCA of the vagina and cervix is increased 24-fold in daughters of women who were exposed to DES *in utero* during the first 16 weeks of pregnancy (28,62). Specific suggested mechanisms of carcinogenesis focus on the retention of nests of abnormal cells of müllerian duct origin, which, after stimulation by endogenous hormones during puberty, are promoted into adenocarcinomas. The median age at diagnosis in the DES-exposed patients is 19 years (28,61), whereas prior to this report, most patients with CCA of the vagina were elderly. The incidence of CCA in the exposed female population from birth to 34 years is estimated to be between 0.14 and 1.4 per 1,000. Approximately 90% of the patients had stage I–II disease at diagnosis and most cases involved the anterior upper third of the vaginal wall. Fortunately, the incidence of this tumor has decreased in recent years, and may decrease even more since the practice of prescribing DES during pregnancy has been discontinued. Palmer et al. (30) assessed the influence of postnatal factors on the development of CCA in women exposed to DES in 244 cases compared with 244 age-matched non-DES-exposed women. Neither oral contraceptive use nor pregnancy was associated with risk of CCA (30).

NATURAL HISTORY OF THE DISEASE (PATTERNS OF SPREAD)

The majority (57% to 83%) of vaginal primaries occur in the upper third or at the apex of the vault, most commonly in the posterior wall; the lower third may be involved in as many as 31% of patients (15,21,33). Lesions confined to the middle third of the vagina are uncommon. The location of the vaginal carcinoma is an important consideration in planning therapy and determining prognosis. Vaginal tumors may spread along the vaginal walls to involve the cervix or the vulva. However, if biopsies of the cervix or the vulva are positive at the time of initial diagnosis, the tumor cannot be considered a primary vaginal lesion. Because of the absence of anatomic barriers, vaginal tumors readily extend into surrounding tissues, such that a lesion on the anterior wall may infiltrate the vesicovaginal septum and/or the urethra; those on the posterior wall may eventually involve the rectovaginal septum and subsequently infiltrate the rectal mucosa. Lateral extension toward the parametrium and paracolpal tissues is not uncommon in more advanced stages of the disease as well as involvement of the obturator fossa, cardinal ligaments, lateral pelvic walls, and uterosacral ligaments.

The issue of regional nodal metastasis, both the incidence of occult nodal disease and the anatomic pathways of lymphatic spread, is somewhat controversial. The incidence of positive pelvic nodes at diagnosis varies with the stage and location of the primary tumor. Because the lymphatic system of the vagina is so complex, any of the nodal groups may be involved, regardless of the location of the lesion (2). Involvement of inguinal nodes is most common when the lesion is located in the lower third of the vagina. There does seem to be a significant risk of nodal metastasis for patients with disease beyond stage I. Although data on staging lymphadenectomy are sparse, 2 studies reported a significant incidence of nodal disease in early-stage vaginal carcinoma. In Al-Kurdi and Monaghan's series (34), the incidence of pelvic nodal metastasis was 14% and 32% for stages I and II, respectively, whereas in the Davis et al. series (24), the incidence was 6% and 26% for stages I and II, respectively. The incidence is expected to be higher for stage

III, although no substantial data are available. Chyle et al. (14) noted a 10-year actuarial pelvic nodal failure rate of 28% and a 16% inguinal failure rate in patients who had local recurrence, in contrast to 4% and 2%, respectively, in the group without local recurrence ($p < 0.001$). The incidence of clinically positive inguinal nodes at diagnosis as reported by several authors ranges from 5.3% to 20% (19,35).

Distant metastasis may occur, primarily in patients with advanced disease at presentation, or those who recurred after primary therapy. In the Perez et al. series (19), the incidence of distant metastasis was 16% in stage I, 31% in stage IIA, 46% in stage IIB, 62% in stage III, and 50% in stage IV. In the largest series reported to date by Hellman et al., distant metastases at diagnosis were rare at 2%, and in 5 of the 7 patients with distant metastases, the tumor involved the entire vagina (36). Robboy et al. reported that metastases to the lungs or supraclavicular lymph nodes represented 35% of recurrences in young women with CCA, a proportion much greater than found with SCC of the cervix or vagina (37).

CLINICAL PRESENTATION

Vaginal Intraepithelial Neoplasia—Carcinoma *In Situ*

VAIN most often is asymptomatic (17). In modern practice, VAIN is usually detected by cytological evaluation performed following hysterectomy as part of a surveillance strategy in patients with a history of CIN or invasive cervical carcinoma. In these cases, VAIN has a predilection for involvement of the upper vagina, likely secondary to a “field effect.” A discharge may be present, but is likely secondary to superimposed vaginal infections. It should be noted that evidence-based guidelines do not support routine cytological studies following hysterectomy for noncervical pathology. The American Cancer Society 2012 guidelines indicated that surveillance cytology in such patients is *not* necessary. Rather, surveillance cytology post hysterectomy should be limited to those patients with a prior history of CIN or invasive cervix cancer (38).

Invasive Squamous Cell Carcinoma

In patients with invasive disease, irregular vaginal bleeding, often postcoital, is the most common presenting symptom followed by vaginal discharge and dysuria. Pelvic pain is a relatively late symptom generally related to tumor extent beyond the vagina (12). In a series of 84 patients with invasive carcinoma, including 55 with SCC, Tjalma et al. noted that 62% of patients had vaginal discharge, 16% had positive cytology, 13% had a mass, 4% had pain, and 2% had dysuria. Forty-seven percent of the lesions were located on the posterior wall and 24% on the anterior wall; 29% had involvement of both walls (39). In 10% to 20% of the patients, no symptoms were reported, and the diagnosis was made by cytological examination.

Other Histologies

The most common presenting symptom in patients with CCA is vaginal bleeding (50% to 75%) or abnormal discharge. More advanced cases may present with dysuria or pelvic pain (26). Cytology is abnormal in only 33% of cases. Therefore, in addition to 4-quadrant cytology, Hanselaar et al. recommended palpation of the entire vaginal vault to assess for submucosal irregularity (40). The majority of CCA lesions are exophytic,

superficially invasive in the upper third of the vault near the cervix.

Embryonal rhabdomyosarcoma, the most common malignant vaginal tumor in children, presents as a protruding, edematous grape-like mass. Ninety percent of these sarcomas present before the age of 5 years. The average age at presentation was 23.5 months in the Maurer et al. series (304). In adults, symptoms most commonly noted were pain accompanied by a mass.

DIAGNOSTIC WORKUP

In general, in patients with suspected vaginal malignancy, thorough physical examination with detailed speculum inspection, digital palpation, colposcopy and cytological evaluation, and biopsy constitute the most effective procedure for diagnosing primary, metastatic, or recurrent carcinoma of the vagina. In symptomatic patients, biopsy of any abnormal exophytic or endophytic lesion noted at the time of the examination is indicated. Examination under anesthesia is recommended for the thoroughness of evaluation of all of the vaginal walls and local extent of the disease, primarily if the patient is in great discomfort because of advanced disease, in order to obtain a biopsy. Biopsies of the cervix, if present, are recommended to rule out a primary cervical tumor. The speculum must be rotated as it is slowly withdrawn from the vaginal fornix, so that the total vaginal mucosa may be visualized, and, in particular, posterior wall lesions, which occur frequently, are not overlooked.

The patient with a history of preinvasive or invasive carcinoma of the cervix found to have abnormal cytology following prior hysterectomy or RT should be offered vaginotomy with application of acetic acid to the entire vault, followed by biopsies as indicated by areas of white epithelium, mosaicism, punctation, or atypical vascularity. It can be very helpful for the menopausal patient or the patient previously irradiated to use a short course of topically applied estrogen (Premarin®) into the vaginal vault once or twice a week for 1 month prior to the colposcopy in order to foster epithelial maturation. Another method of identifying the area(s) most in need of biopsy would be, after application of acetic acid, to apply half-strength Schiller's iodine to determine if the Schiller-positive (nonstaining) areas correspond with the involved areas identified following acetic acid application.

Table 20.1A FIGO Staging System for Carcinoma of the Vagina

Stage	Description
Stage I	Limited to the vaginal wall
Stage II	Involvement of the subvaginal tissue but without extension to the pelvic side wall
Stage III	Extension to the pelvic side wall
Stage IV	Extension beyond the true pelvis or involvement of the bladder or rectal mucosa. Bullous edema as such does not permit a case to be allotted to Stage IV
IVA	Spread to adjacent organs and/or direct extension beyond the true pelvis
IVB	Spread to distant organs

STAGING

The 2 commonly used staging systems for carcinoma of the vagina are the International Federation of Gynecology and Obstetrics (FIGO) (Table 20.1A) (43) and the American Joint Commission on Cancer (AJCC) classifications (Table 20.1B) (44). According to FIGO and AJCC guidelines, cases should be classified as vaginal carcinomas only when “the primary site of the growth is in the vagina.” A tumor of the vagina that involves the cervix or vulva should be classified as a primary cervical or vulvar cancer, respectively. It may be difficult or impossible histologically to distinguish a primary vaginal SCC from recurrent cervical or vulvar disease. In this setting, it is unclear whether the vaginal lesion represents a new carcinoma of the vagina, recurrent cervical cancer, or a HPV-related field effect in these

Table 20.1B American Joint Commission on Cancer Staging of Vaginal Cancer

Primary Tumor(T)/FIGO	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis/	Carcinoma <i>in situ</i> (preinvasive carcinoma)
T1/I	Tumor confined to the vagina
T2/II	Tumor invades paravaginal tissues but not to the pelvic wall
T3/III	Tumor extends to the pelvic wall
T4/IVA	Tumor invades mucosa of the bladder or rectum and/or extends beyond the pelvis (Bullous edema is not sufficient to classify a tumor as T4)
Regional Lymph Nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph nodes
N1/III	Pelvic or inguinal lymph node metastasis
Distant Metastasis (M)	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1/IVB	Distant metastasis
AJCC Stage Groupings	
Stage 0	Tis N0 M0
Stage I	T1 N0 M0
Stage II	T2 N0 M0
Stage III	T1–3 N1 M0, T3 N0 M0
Stage IVA	T4, any N, M0
Stage IVB	Any T, any N, M1

Source: American Joint Committee on Cancer (AJCC). Vagina. In: Edge SB, Byrd DR, Compton CC, et al., eds. *AJCC Cancer Staging Manual*. 7th ed. New York, NY: Springer-Verlag; 2010:469–472. Used with permission.

patients. Therefore, cervical cytology should be obtained, and directed biopsies if indicated based on abnormal cytology. If a cervical abnormality is visualized or palpated, biopsy is recommended to rule out a primary cervical malignancy. Similarly, the vulva should be carefully inspected, including application of acetic acid, with directed biopsies of abnormally staining epithelium.

Additionally, in the setting of a prior gynecologic malignancy, a neoplasm would be classified as primary carcinoma of the vagina if the current vaginal tumor occurred 5 or more years after the initial cancer diagnosis and if there is no other clinical evidence of recurrence of the initial gynecologic lesion (45).

Perez et al. (46) proposed in 1973 that FIGO stage II vaginal cancer should be subdivided into stage IIA (tumor infiltrating the subvaginal tissues but not extending into the parametrium) and stage IIB (tumor infiltrating the parametrium but not extending to pelvic side walls). However, most investigators do not use this classification, and there are few published data to support the prognostic significance of this subclassification (19,47). In addition, FIGO does not assign a specific stage for those patients with inguinofemoral lymphadenopathy. Some authors assign these patients to stage III, whereas others consider them stage IVB. In the AJCC staging system, patients with T1–3 and positive nodes (pelvic or inguinal) are assigned to stage III (44).

At present, primary malignancies of the vagina are all staged clinically. In addition to a complete history and physical examination, routine laboratory evaluations including complete blood cell count (CBC) with differential and platelets, and assessment of renal and hepatic function should be undertaken. In order to determine the extent of disease, the following tests are allowed by International Federation of Gynecology and Obstetrics (FIGO) criteria: chest radiograph, a thorough bimanual and rectovaginal examination, cystoscopy, proctoscopy, and intravenous pyelogram. Cystoscopy and/or proctosigmoidoscopy should be performed on patients with symptoms suggestive of bladder and/or rectal infiltration, respectively. If the patient is in significant discomfort, the examination should be conducted under anesthesia, preferably by a radiation oncologist and gynecologic oncologist who will be involved in her ongoing care. However, it can be difficult even for the experienced examiner to differentiate between disease confined to the mucosa (stage I) and disease spread to the submucosa (stage II) (13,33,48).

Pelvic computed tomography (CT) scan is generally performed to evaluate inguinofemoral and/or pelvic lymph nodes, as well as extent of local disease. In patients with vaginal melanoma or sarcoma, chest, abdomen, and pelvic CT scans are often part of the workup. Magnetic resonance imaging (MRI) has emerged as a potentially important imaging modality in the evaluation of vaginal cancers, predominantly intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images (49). Taylor et al. (49) concluded that MRI identified over 95% of primary vaginal tumors and enabled radiologic staging, which correlated with outcomes. An additional role of MRI is differentiation of tumor from fibrotic tissue in patients with suspected recurrent vaginal carcinoma (50).

Positron emission tomography (PET) is evolving as a modality of potential use in the evaluation of vaginal cancer that allows detection of the extent of the primary as well as abnormal lymph nodes more often than does CT scan. PET/CT was evaluated in a prospective registry study in 23 patients comparing the results of CT and whole-body PET (51). CT visualized the intact primary tumor in 43% of patients as compared to PET, which visualized 100% of all intact primary tumors. Furthermore, all abnormal lymph nodes visualized by CT were also detected by PET, with the addition of 4 additional foci consistent with nodal metastasis found on PET imaging (51).

In modern practice, for the majority of patients with disease volume and/or location requiring definitive RT to achieve

Non-Hodgkin's lymphoma

Leukemia/myeloid sarcoma

cure, therapeutic planning will be guided by disease volume assessment utilizing CT, MRI, and/or PET/CT, even though such radiologic modalities are not “allowed” for purposes of staging.

PATHOLOGIC CLASSIFICATION

Table 20.2 illustrates the current pathologic classification.

SCC and Precursors

SCCs (Fig. 20.2) comprise 67% to 80% of vaginal malignant tumors (52,53). SCCs of various sites are very difficult or impossible to differentiate on either a morphologic or an immunohistochemical basis. Vaginal invasive and *in situ* SCCs both occur with greatly increased frequency in patients with a history of cervical SCC. The standardized incidence ratio, the observed vaginal invasive cancer cases in patients with a history of cervical cancer divided by the number of expected cases based on demographic factors, is 29.9 (54). For vaginal SCC *in situ*, the standardized incidence ratio is 53.8 (54).

In contrast to cervical SCC, many vaginal SCCs are HPV negative. HPV has been detected in 50% to 80% of primary vaginal SCCs (56–59). Type 16 is the most common, present in 33% to 56% of cases (57–59). HPV positive tumors are likely to be associated with a history of previous SCC of the cervix or vulva, while patients with HPV negative carcinomas will usually not have a history of a previous HPV-related carcinoma (59). As in some other anatomic sites, immunohistochemical staining for p16^{INK4A} is highly sensitive (96%) and specific (86%) for the presence of HPV (59).

HPV-related carcinomas are frequently nonkeratinizing and of basaloid or warty subtypes (59). The presence of HPV does not correlate with clinical stage, tumor grade, or tumor size (56). In one study, overall prognosis did not differ significantly between the HPV positive and HPV negative groups (56). Among high stage (FIGO III or higher) patients, however, those positive for HPV had improved disease-free and overall survival (56).

SCCs may be subdivided into keratinizing and nonkeratinizing types and basaloid, warty (condylomatous), and papillary squamotransitional variants have been described (53,55). Basaloid carcinomas are composed of nests of high nucleus-to-cytoplasm ratio cells with very little evidence of squamous differentiation. Warty carcinomas have exophytic growth with papillae with fibrovascular cores and prominent koilocytotic atypia. Papillary squamotransitional carcinomas histologically closely resemble papillary urothelial carcinomas. The prognostic significance, if any, of these variants is not yet established. In a recent study, all the variants evaluated were strongly associated with HPV infection (58).

Verrucous carcinoma is a distinct type of very well differentiated SCC that presents as an exophytic, fungating mass and microscopically has very bland nuclear cytology, usually lacks stromal cores in the papillae, usually lacks koilocytotic atypia, and has a tendency to recur locally rather than metastasize (53,55). It is so well differentiated that it is notoriously difficult to diagnose on small or superficial biopsies that do not allow recognition of the pushing border of the broad epithelial cell nests at the deep aspect of the lesion. These tumors are resistant to radiation treatment and may, following irradiation, appear as a higher-grade SCC, and so treatment is usually surgical (53).

Tumors are graded based on their degree of differentiation, with keratinizing tumors with abundant cytoplasm being considered well-differentiated (grade 1), those with less abundant cytoplasm yet easily recognizable as squamous being considered moderately differentiated (grade 2), and nonkeratinizing tumors that are not easily recognizable as squamous being considered poorly differentiated (grade 3). Squamous carcinomas may have areas of sarcomatoid change, considered a pattern of poorly differentiated carcinoma. Grade is not a significant predictor of prognosis (53,56).

FIGURE 20.2. Primary vaginal squamous cell carcinoma with focal clear cytoplasm. Some examples of squamous cell carcinoma may have focally prominent clear cytoplasm. This should not be mistaken for clear cell carcinoma or other types of adenocarcinoma. There is a dense lymphoplasmacytic infiltrate surrounding the invasive carcinoma and there is overlying dysplastic squamous epithelium.

FIGURE 20.3. Vaginal squamous cell carcinoma *in situ* (vaginal intraepithelial neoplasia 3). There is full thickness loss of squamous cell maturation in the form of cells with large, atypical nuclei and very scant cytoplasm extending up to the surface of the epithelium. This patient previously had a cervical adenocarcinoma and was treated with radiation therapy. Stromal cell atypia consistent with the history of radiation treatment, seen as stromal cells with markedly enlarged nuclei and a stellate appearance, can be seen in the lower right corner of the photograph.

The histological diagnosis of VAIN depends on nuclear atypia, loss of squamous cell maturation, and the presence of suprabasilar mitoses in the squamous epithelium of the vagina. Hyperkeratosis, papillomatosis, and atypical mitotic figures are seen in some cases. VAIN is graded on a 3-grade scale similar to cervical intraepithelial neoplasia, based on whether the abnormality is primarily limited to the lower one-third of the epithelium (VAIN1/mild squamous dysplasia), the lower two-thirds (VAIN2/moderate squamous dysplasia), or nearly the full thickness (VAIN3/severe squamous dysplasia/SCC *in situ*) (Fig. 20.3). Human papillomavirus effect/koilocytotic atypia, while seen near the surface of the epithelium, is not considered loss of maturation and is equivalent to VAIN1. Some authors have advocated use of Bethesda System terminology: low-grade

squamous intraepithelial lesion (LSIL) being equivalent to VAIN1 and high-grade squamous intraepithelial lesion (HSIL) being equivalent to VAIN2–3 (55).

VAIN1 is appropriately considered a premalignant lesion as high risk HPV types have been identified in 76% of VAIN1 lesions, with low-risk types in the remainder (60). VAIN2–3 almost always has detectable high risk HPV DNA, with HPV type 16 being the most common type, present in 50% to 54% of cases (55,60). The natural history of untreated VAIN is not well understood, but with treated cases there is an approximately 5% risk of progression to invasive SCC (53).

Glandular Tumors and Precursors

Vaginal CCS (Fig. 20.4) are grossly nodular or polypoid. Microscopically, these tumors are similar to clear cell carcinoma (CCC) of the ovary or endometrium and they are composed of variable sized glands lined by cuboidal epithelium with variable nuclear enlargement and atypia (53). The cytoplasm may be clear due to cytoplasmic glycogen, but this is not a requirement for diagnosis and some cases may have scant or predominantly eosinophilic cytoplasm. Some tumor cells may have large nuclei that protrude into the glandular lumens (“hobnail cells”). A tubulocystic pattern, with variable sized glands, sometimes with areas of flattened epithelium and papillary tufting, is characteristic, but solid and papillary patterns may also be seen (55). Most cases will have associated vaginal adenosis.

The most critical histological differential diagnostic consideration is Arias-Stella reaction (such as in vaginal endometriosis), so patient history concerning the presence or absence of current or recent pregnancy should be obtained. Microglandular hyperplasia, which may occur in adenosis as well as in the endocervix, may also enter the differential diagnosis (53). Vaginal metastases of renal cell carcinoma have been reported with some frequency, sometimes preceding the diagnosis of a renal tumor, and may need to be excluded with immunohistochemical evaluation (53).

Vaginal adenosis, the presence of müllerian-type glandular epithelium in the vagina, is related to prenatal DES exposure

FIGURE 20.4. High magnification view of a vaginal clear cell carcinoma. The characteristic tubulopapillary architecture is seen with glands lined by cuboidal epithelium with prominent scalloped luminal surfaces and nuclei that protrude into the gland lumens (“hobnail nuclei”). There are occasional papillae that extend into the spaces and single tumor cells that appear to lie unattached within the gland lumens. There is high-grade nuclear atypia and marked hyperchromatism in some of the nuclei. Typically, clear cytoplasm is focally present but much of the malignant epithelium has scant or eosinophilic cytoplasm.

and is the precursor lesion for CCC, but can also be seen in non-DES-exposed women. Microscopically, the involved mucosa may have glandular epithelium at the surface or glands in the lamina propria. The glandular epithelium may be mucinous, tuboendometrial (which may be ciliated), or composed of cuboidal embryonic type cells (55). While a risk factor for CCC, most cases will spontaneously regress (55). When adenosis is seen in association with a CCC, the adenosis is likely to be cytologically atypical and of the tuboendometrial type (53).

Primary vaginal adenocarcinomas not associated with DES exposure have a much higher median age at presentation (54 years) than DES-associated cases (63). Prognosis is significantly worse than other primary carcinomas, with a 5-year survival rate of 34%, compared to 58% for SCC (63) and 93% for DES-associated CCC (53).

While endometrioid adenocarcinoma involving the vagina is most commonly of endometrial origin, primary endometrioid adenocarcinoma also occurs. It is the second most common type of primary vaginal adenocarcinoma (after CCC) (64). In one series of 18 cases, the mean patient age was 60 years, 16 patients had previously had a hysterectomy, 14 patients had vaginal endometriosis (a presumed precursor lesion), and none of the patients had a history of DES exposure (64). These tumors have histologic features typical of endometrial endometrioid adenocarcinomas: glandular architecture with columnar cells and flat luminal borders and squamous or mucinous metaplasia in some cases (64). In some cases, papillary architecture may suggest a diagnosis of serous carcinoma or squamous metaplasia with cytoplasmic glycogen may suggest a diagnosis of CCC, but careful attention to the morphology of the glandular areas and the usual presence of associated endometriosis may be helpful in diagnosing endometrioid adenocarcinoma. As primary vaginal adenocarcinomas are much less common than secondary tumors, the possibility of a primary tumor in the endometrium, ovary, and colon must be carefully excluded (64).

Primary serous adenocarcinoma has been reported as a primary tumor in the vagina. Metastasis from the endometrium or ovary must be excluded. CCC is also in the differential diagnosis as it may have papillary architecture and lack clear cytoplasm and may easily be confused with serous carcinoma. A recent carcinoma in a patient with possible *in utero* DES exposure was reported as “grade 2/3 clear cell and focal papillary serous carcinoma,” but not histologically illustrated (65).

Primary vaginal mucinous adenocarcinoma resembling cervical mucinous adenocarcinoma (lacking goblet cells) has been reported following hysterectomy, presumably arising from adenosis or endocervicosis (66). Exclusion of a metastasis, especially from the endocervix, endometrium, or ovary, is necessary to establish this diagnosis.

Very rare cases of primary vaginal adenocarcinoma of intestinal type have been reported (67). These tumors are not related to DES exposure and are composed of mucin-producing malignant glands, often with intraluminal nuclear debris (“dirty necrosis”) (67). Immunohistochemically, these tumors are diffusely positive for CDX-2 and cytokeratin 20, markers of intestinal differentiation (not necessarily origin), so clinical, endoscopic, and radiologic exclusion of origin from a colorectal, endometrial, ovarian, or other primary is necessary to establish this diagnosis (67).

Mesonephric adenocarcinoma, carcinoma thought to arise from the remnants of the mesonephric ducts, is one of the rarest primary vaginal tumors. The mean patient age in one series was 41 years, and the presentation may be a multicystic vaginal mass (68). The tumors histologically are seen as crowded glands or tubules composed of low columnar or cuboidal epithelium containing eosinophilic secretion (69). A variety of patterns may be seen, but the glandular (ductal) pattern is the most common and may closely resemble an endometrioid adenocarcinoma (68). Association with mesonephric remnants, present in the lateral wall of the vagina, or mesonephric hyperplasia, is key

to recognizing a tumor as a mesonephric carcinoma (68). The tumor cells lack clear cytoplasm and staining for mucin and glycogen are negative, but PAS staining may demonstrate basement membrane material around the tubules (55). The immunohistochemical profile, positive for cytokeratin AE1/AE3, cytokeratin 5/6, CD10, vimentin, and calretinin and negative for carcinoembryonic antigen, cytokeratin 20, estrogen receptor protein, and progesterone receptor protein, may be useful for differentiating this tumor from other adenocarcinomas (68,69). The prognosis of these rare tumors is not yet well established, but may be better than that of müllerian adenocarcinomas (68). Some cases may have an associated spindle cell component (malignant mixed mesonephric tumor) and may have heterologous elements such as rhabdomyosarcoma or atypical cartilage (68).

As primary vaginal carcinomas are rare and metastases relatively common, metastatic carcinoma should always be considered in the differential diagnosis of a glandular vaginal tumor. Metastases may be from a number of sites that may have relatively large undiagnosed primary tumors, such as the uterus, ovary, and kidney. Pancreatic carcinoma may also present with vaginal metastases (70). Isolated vaginal metastases of rectal adenocarcinoma have been seen and may respond well to local excision and chemotherapy (71).

Pagetoid adenocarcinoma *in situ* has been seen involving vaginal epithelium, believed to represent direct extension from origin in the cervix (72). The cells are admixed with the squamous epithelium, have pale cytoplasm, and stain immunohistochemically with cytokeratin 7 and p16 (73). Extension of Paget's disease of the vulva into the vaginal epithelium is also a consideration.

Other Epithelial Tumors

Adenosquamous carcinomas compose approximately 2% of primary vaginal carcinomas (55). These tumors are composed of a mixture of glandular and squamous components, lack associated adenosis or endometriosis, and may behave aggressively.

Primary glassy cell carcinoma has been the subject of a single case report (73). Glassy cell carcinoma is considered a variant of poorly differentiated adenosquamous carcinoma with poor prognosis (73). The tumors are histologically composed of nests of cells with abundant eosinophilic or amphophilic cytoplasm with a "ground glass" appearance, prominent cell membranes, large nuclei, and cytoplasmic mucin positivity (73).

Adenoid cystic carcinoma may involve the vagina, but if seen on a biopsy, it is likely to be of Bartholin gland origin and would be considered a vulvar, rather than vaginal, primarily (74). These tumors are composed of nests of basaloid epithelial cells with cribriform architecture with hyaline stroma (composed of basement membrane-like material and mucin) within the rounded spaces. Perineural invasion is commonly seen.

Primary vaginal small cell (neuroendocrine) carcinoma is very rare with fewer than 25 cases reported (75). The mean age at presentation is 59 years and postmenopausal bleeding is the usual presenting symptom (75). Most small cell carcinomas will express a neuroendocrine marker such as synaptophysin. Secondary involvement of the vagina by a cervical or other neuroendocrine carcinoma must, of course, be excluded in order to establish this diagnosis. TTF-1, an immunohistochemical stain often used as a marker of lung or thyroid origin is frequently positive in extrapulmonary small cell carcinomas so immunoreactivity does not prove that a tumor is metastatic at this site. Prognosis is very poor with only about 15% of patients surviving more than 1 year (75). Primary vaginal small cell carcinoma may cause Cushing syndrome due to adrenocorticotrophic hormone production by the tumor (76).

Vaginal paraganglioma is another epithelioid tumor that has been the subject of single case reports (77,78). These tumors have a characteristic nested pattern with round or polygonal cells

with granular eosinophilic cytoplasm, expression of chromogranin and synaptophysin, and absence of expression of keratin AE1/AE3, actin, desmin, and HMB-45 (77,78). Catecholamine hypersecretion is a potential concern during biopsy or surgical treatment (78).

Mixed Epithelial and Mesenchymal Tumors

Carcinosarcoma/malignant mixed müllerian tumor (MMMT) has been reported as a primary vaginal tumor (79). The epithelial component in the reported cases of primary vaginal MMMT is usually SCC (79). Absence of sarcomatoid component keratin staining has been suggested as a criterion for differentiating MMMT (sarcomatoid component keratin negative) from sarcomatoid carcinoma (sarcomatoid component keratin positive) (79). Because the epithelial component is usually squamous and because a recent case was associated with VAIN3 and high-risk human papillomavirus infection (79), it could be argued that these cases likely represent sarcomatoid carcinomas with loss of sarcomatoid component keratin expression.

Myoepithelial neoplasms similar to those more commonly seen in the salivary glands, with oval epithelioid cells with co-expression of keratin and desmin and/or smooth muscle actin, have been reported (80). The examples from the vagina have been benign (80).

Mesenchymal Tumors

Sarcomas represent 3% of primary vaginal cancers. There are several primary mesenchymal tumors that may occur in the vagina and the histologic diagnosis of this group of tumors may be very challenging. There are 2 tumors, rhabdomyosarcoma and leiomyosarcoma, that are of special interest because of their relative frequency at this site. Before establishing a diagnosis of a primary vaginal sarcoma, however, a variety of other lesions with spindle cell morphology must be excluded including sarcomatoid carcinoma, spindle cell melanoma, leiomyosarcoma or endometrial stromal sarcoma of uterine origin, and metastatic sarcoma. Mesenchymal tumors can be grouped as predominantly round cell tumors, spindle cell tumors with high cellularity, and spindle cell tumors with low cellularity.

The most important round cell mesenchymal tumor at this site is rhabdomyosarcoma (also known as sarcoma botryoides), the most common sarcoma of childhood (Fig. 20.5). Genital tract rhabdomyosarcoma may involve the vagina or the cervix and accounts for only 0.003% of genital tract malignancies (81). The median patient age at presentation is 2 years (82), but rare cases may occur in adults (55). Pediatric rhabdomyosarcomas are of embryonal subtype in 95% of cases and the botryoid variant was the most common, 80% of the total cases (82).

The tumors are commonly polypoid (or similar in appearance to a bunch of grapes, leading to the designation "botryoides") and are composed histologically of poorly differentiated tumor cells with overlying benign squamous epithelium. There may be a hypercellular band composed of cells with very little visible cytoplasm immediately deep to the squamous epithelium (cambium layer). Below this, the cellularity is variable and may be sparse with cytologically atypical round or occasionally spindle-shaped nuclei widely spaced in edematous stroma. Mitotic figures are usually frequent and the Ki-67 labeling index is high. Histologically recognizable skeletal muscle differentiation in the form of strap cells is not always seen and is not a requirement for diagnosis. Immunohistochemical staining for desmin and muscle-specific actin (muscle markers) and myoglobin and myogenin (striated muscle markers) may be useful in confirming the diagnosis (53,55).

FIGURE 20.5. High magnification view of a primary vaginal rhabdomyosarcoma showing markedly pleomorphic nuclei and occasional cylindrical cells with eosinophilic cytoplasm representing skeletal muscle differentiation (“strap cells”). The patient was an elderly woman who presented with a vaginal mass. An endometrial curettage was negative for tumor, so the tumor was believed to represent a vaginal primary. There was extensive necrosis so it is possible that this tumor is a component of a malignant mixed müllerian tumor, with the epithelial component being unsampled or entirely necrotic.

The highly cellular spindle cell mesenchymal tumors include leiomyosarcoma, gastrointestinal stromal tumor, solitary fibrous tumor, and synovial sarcoma. In some cases, particularly when presented with a small biopsy specimen, immunohistochemical stains may be very helpful in this differential diagnosis. Smooth-muscle neoplasms will stain for actin, desmin, and caldesmon; gastrointestinal stromal tumor for c-Kit/CD117 and CD34; solitary fibrous tumor for CD34 (but not c-Kit/CD117); and synovial sarcoma will sometimes, unusually for a sarcoma, stain for epithelial membrane antigen and/or keratin.

Smooth muscle neoplasms are composed of fascicles of cells with oval to elongated nuclei and eosinophilic cytoplasm. Vaginal smooth muscle tumors may be benign or malignant. Leiomyomas are the most common vaginal stromal tumors, may have a similar presentation compared to leiomyosarcoma, and may enlarge rapidly during pregnancy (55). Histologic criteria have varied over time, but a smooth muscle tumor over 3 cm with 5 or more mitotic figures per 10 high power fields and moderate to marked cytologic atypia should be considered a leiomyosarcoma (53,55). Some leiomyomas from pregnant women may have increased mitotic activity (55).

Leiomyosarcomas are the most common vaginal sarcoma in adults and present most commonly with vaginal bleeding in a patient above the age of 40 (53,55). Histologically, they are similar to the much more common uterine leiomyosarcomas. These tumors invade locally and have hematogenous metastases. Primary treatment is surgical and the 5-year survival of approximately 35% (53).

Gastrointestinal stromal tumors (GIST) may rarely present as a rectovaginal septal mass and in this situation they are likely to be misdiagnosed as a smooth muscle tumor (83,84). Correct diagnosis of this tumor is important because of the malignant potential of this tumor, the lack of effectiveness of conventional chemotherapy and radiotherapy, and because of the existence of specific treatment (Imatinib mesylate) for this tumor (83,84). GISTs in this location are spindle cell tumors with a median mitotic count of 15 per 10 high power fields (83). Immunohistochemical stains for KIT (CD117) and CD34 are positive and stains for desmin and estrogen receptor protein are negative (84).

Primary vaginal solitary fibrous tumors are extremely rare, but have been reported as a single case report (85). These are spindle cell tumors with bland nuclear cytology, disorganized architecture (“patternless pattern”), and dilated branching blood vessels. Immunohistochemical staining for CD34 is positive and staining for muscle markers is either negative or only focally positive (85). Despite the absence of key indicators of malignant behavior in stromal tumors such as mitotic activity and necrosis, recurrence may be seen following excision (85).

Synovial sarcoma, more common in the extremities, has recently been reported in a variety of other sites including the female genital tract (86,87). The tumors may be monophasic with only a highly cellular, mitotically active spindle cell component or they may be biphasic and also have foci of gland-like structures lined by a single layer of cuboidal epithelium (87). Expression of keratin by a spindle cell carcinoma may be helpful in suggesting the diagnosis and molecular genetic demonstration of the X;18 translocation or rearrangement of the *SYT* gene is confirmatory (86,87).

A variety of malignant or potentially malignant mesenchymal tumors, more commonly seen at other sites, may very rarely present as a vaginal mass. Primary low-grade endometrial stromal sarcoma, arising in endometriosis, has been reported (55). CD10 immunoreactivity and absence of staining for muscle markers would be important in establishing this diagnosis. Primary malignant peripheral nerve sheath tumor has been reported, in association with neurofibromatosis, type 1 (88). The reported case was initially misdiagnosed as a smooth-muscle neoplasm, but immunohistochemical staining for S-100 protein and lack of expression of smooth muscle markers, CD10, and HMB-45 helped to exclude a smooth muscle neoplasm, endometrial stromal sarcoma, or spindle cell melanoma (88).

Several spindle cell mesenchymal tumors of lower cellularity may be seen. Within this morphologic grouping of tumors, the major consideration is distinguishing aggressive angiomyxoma from the other, less aggressive, lesions. Aggressive angiomyxoma is an infiltrative neoplasm with frequent local recurrence. The tumor has been clinically mistaken for a vaginal cyst (89). This tumor is characterized grossly by poor circumscription and a gelatinous consistency and histologically by spindle and stellate cells in myxoid stroma and blood vessels of varying size including thick-walled vessels (84, 89). Immunohistochemical staining for estrogen receptor protein, progesterone receptor protein, desmin, and CD34 are positive, but these markers also label the other tumors in this differential diagnosis (84). HMGA2, the product of a transcription factor gene subject to rearrangement in aggressive angiomyxoma, may prove to be useful in the differential vs. the histologically similar lesions (84). Initial treatment is surgical, but treatment of recurrent tumors with hormonal therapy or radiotherapy has also been attempted (89).

Angiomyofibroblastoma and myofibroblastoma are related mesenchymal tumors that may occur in the vulva or vagina and may be related to tamoxifen treatment (90,91). Angiomyofibroblastoma is a circumscribed, nonencapsulated, cytologically bland, spindle cell tumor with variable cellularity, edematous zones, prominent thin-walled vessels, and insignificant mitotic activity (84,90). Stromal lymphocytes and mast cells, multinucleate cells, and tumor cell aggregation around blood vessels may be seen in some cases (84). Immunohistochemical staining for vimentin, desmin, PTEN, CD34, estrogen receptor protein, and progesterone receptor protein are expected to be positive, and that for smooth-muscle actin and S-100 protein will be negative (90). Angiomyofibroblastoma is benign but must be distinguished from the aggressive angiomyxoma (90).

Myofibroblastoma is a spindle cell tumor that arises from the subepithelial stroma of the vagina and is usually not associated with tamoxifen treatment (91). The cells may be ovoid or stellate, are arranged among thick collagen bands, and stain immunohistochemically for vimentin, desmin, and CD99 while

staining for smooth muscle actin is negative (91). These tumors may recur locally, but metastasis has not been reported (91).

Occasional stromal tumors may have epithelioid morphology, composed of round or polygonal cells with abundant cytoplasm in a solid pattern. Once the possibility of a carcinoma, a neuroendocrine tumor (such as carcinoid tumor or paraganglioma), or a melanoma have been excluded, there are a variety of epithelioid stromal tumors that are potential diagnostic possibilities. These include a smooth-muscle tumor or GIST with epithelioid morphology, granular cell tumor, alveolar soft part sarcoma, and perivascular epithelioid cell tumor.

Primary vaginal perivascular epithelioid cell tumor has been the subject of reports of single cases in an adult (92) and in a child (93). These tumors, also known as PEComa, clear cell myomelanocytic tumor, or extrapulmonary clear cell sugar tumor, are composed of sheets of tumor cells with central round nuclei, prominent nucleoli, and abundant eosinophilic or clear cytoplasm (92,93). Pigment production by the tumor may be prominent and the tumors stain immunohistochemically for HMB-45, desmin staining is variable, and they are negative for S-100 protein, keratin, chromogranin, and synaptophysin (92,93). The cellular morphology, pigment, and HMB-45 expression could potentially lead to confusion with melanoma, but the absence of staining for S-100 and variable staining for desmin may be helpful.

Miscellaneous Tumors

Primary vaginal malignant melanomas comprise 3% to 8% of primary vaginal malignant tumors (52,55). In the NCDB report by Creasman et al. (5), vaginal melanomas represented 4% of primary vaginal cancers. Trimble's examination of the Surveillance, Epidemiology, and End Results (SEER) data on 30,295 melanomas found 51 vaginal melanomas (0.3% of all melanomas), with an annual incidence of 0.026 per 100,000 (32). They most commonly present with vaginal bleeding, usually involve the distal one-third of the vagina, and have a mean age at presentation of 61 years (94). The tumors are commonly nodular, ulcerated, and pigmented, but they may also be amelanotic (55). Microscopically, melanomas may have rounded, epithelioid cells or be composed of spindle-shaped cells. Adenocarcinoma or poorly differentiated squamous carcinoma (in the case of melanomas with rounded cells) or sarcoma or sarcomatoid carcinomas (in the case of spindle cell melanoma) may be differential diagnostic considerations and immunohistochemical staining for S-100 protein, HMB-45, and MelanA are often helpful in confirming the diagnosis of melanoma. Excluding metastatic melanoma may be difficult, but the presence of an extensive lateral junctional component would favor a primary melanoma (53) and a history of melanoma elsewhere would certainly raise the possibility of metastasis.

Clark's level, assigned based on histologic levels in the skin, is not appropriate at this site, but depth of invasion (measured in mm) should be reported. Almost all cases are greater than 2 mm in depth (53). In a recent series of stage I cases, the median tumor size was 3.0 cm and the median depth of invasion was 7 mm (94). Of the patients surgically treated with lymph node dissection, 25% had positive pelvic or inguinal lymph nodes (94). The reported prognosis is worse than that of cutaneous melanoma, with 5-year survival rates of 5% to 20% for vaginal melanoma (53,55).

The vagina is the primary site of rare pediatric extragonadal yolk sac tumors. These tumors (also known as endodermal sinus tumor) may clinically present similarly to rhabdomyosarcoma, with a friable polypoid mass associated with vaginal bleeding in a child (95,96). Most of the reported tumors have been in patients 4 years of age or younger (53). Serum α -fetoprotein elevation may be helpful in suspecting the diagnosis. Histologically,

these tumors may have a variety of histologic patterns, but a mesh-like microcystic pattern with hyaline globules is commonly seen (96). Reticular, solid, and papillary patterns, sometimes with columnar cells surrounding a fibrovascular core (Schiller-Duval bodies) may also be seen (53,96). Immunohistochemical staining for α -fetoprotein may be helpful if positive, but is poorly sensitive. Glypican 3 and SALL4 are newer, more sensitive, markers for yolk sac tumor that have recently been used investigated at other sites and may also be useful for vaginal yolk sac tumor (97–99). Correct diagnosis is critical as these tumors respond well to platinum-based chemotherapy and surgical treatment may not be necessary (95).

Along with rhabdomyosarcoma (see above) and hematolymphoid neoplasms (see below), a few rare sarcomas are possible considerations in the small round cell tumor differential diagnosis. Peripheral primitive neuroectodermal tumor and Ewing sarcoma are considered related neoplasms that show neuroectodermal differentiation and share characteristic chromosomal translocations, usually t(11;22), which result in fusion of the *EWSR1* and *FLI-1* genes (100). These are very rare tumors, which usually present in young adults (100,101). Histologically, the tumors are lobulated at low magnification with solid cellular aggregates separated by fibrous septae. At high magnification, the tumor cells have relatively uniform hyperchromatic nuclei and scant to moderately abundant eosinophilic cytoplasm. Squamous and glandular differentiations are not seen and only a minority of cases will have rosette formation by the tumor cells (100). Immunoreactivity for *CD99* and *FLI-1*, absence of staining for muscle markers, and molecular identification of the characteristic t(11;22) are confirmatory (100,101). Reverse transcriptase polymerase chain reaction or fluorescent *in situ* hybridization molecular studies are considered the “gold standard” for the diagnosis of these tumors (100).

A single case of primary vaginal extrarenal teratoid Wilms tumor (nephroblastoma) has recently been reported (102). This tumor had areas of undifferentiated malignant cells (blastoma component), but the spindle cell and epithelial/tubular component typical of Wilms tumor were also present along with heterologous cartilage, skeletal muscle, squamous epithelium, and mucinous epithelium (103).

Hematolymphoid Tumors

Primary non-Hodgkin's lymphoma of the female genital tract is rare, less than 1% of extranodal lymphomas, but secondary involvement in advanced lymphoma is significantly more common. The mean patient age is approximately 52 years and patients may present with a mass, vaginal bleeding, or urinary symptoms (104). Lymphoma limited to the vagina has been the subject of occasional case reports and may clinically closely mimic a carcinoma (105,106). Very rare reports of other tumors such as plasmacytoma and eosinophilic granuloma also exist (55).

Correct preoperative diagnosis of extranodal non-Hodgkin's lymphomas is essential to avoid radical surgery and allow specific treatment. “B symptoms” such as fever, weight loss, night sweats, and fatigue are usually absent (105). The differential diagnosis may include inflammatory conditions and a variety of tumors that may have inconspicuous cytoplasm including small cell carcinoma, melanoma, endometrial stromal sarcoma, and primitive neuroectodermal tumors (104). The tumors may be diffuse large B-cell lymphomas or follicular lymphomas (104,105). One recently reported case of primary vaginal diffuse large B-cell lymphoma was associated with immune thrombocytopenic purpura (107).

Myeloid sarcoma, a tumor composed of malignant myeloblasts, is also known as granulocytic sarcoma and chloroma. These tumors may present as a vaginal mass in the absence of a history of acute myeloid leukemia (AML), although patients

presenting with myeloid sarcoma will generally progress to AML relatively rapidly (108). Histologically, the tumors are composed of small to intermediate size cells with scant cytoplasm, fine chromatin, and frequently with crush artifact (108). Immunohistochemical staining for keratin and neuroendocrine markers, muscle markers, melanoma markers, and B- and T-cell markers will be negative (108). Myeloperoxidase, lysozyme, CD43, and CD68 are among the useful positive markers for this potentially difficult to diagnose neoplasm (108).

PROGNOSTIC FACTORS INFLUENCING CHOICE OF TREATMENT

Invasive SCC

As with most primaries, stage of disease is the dominant prognostic factor in terms of ultimate outcome (14,16,18,19,35, 109–120). In Perez's series, including 212 patients with primary vaginal carcinomas treated with definitive RT, the 10-year actuarial disease-free survival was 94% for Stage 0, 80% for Stage I, 55% for Stage IIA, 35% for Stage IIB, 38% for Stage III, and 0% for those with Stage IV (35). In a recent SEER analysis of over 2000 patients by Shah et al., the 5-year disease-specific survival was 84% for stage I, 75% for stage II tumors, and 57% for women with advanced disease (121).

The impact of lesion location has been controversial. Several investigators (14,23,122,123) have shown better survival and decreased recurrence rates for patients with cancers involving the proximal half of the vagina when compared with those in the distal half or those involving the entire length of the vagina. Tarraza et al. (124) reported that upper-third lesions develop local recurrences more frequently, and lower-third lesions develop a disproportionate number of sidewall and distant recurrences. Chyle et al. (14) observed a 17% rate of pelvic relapse in patients with upper vaginal tumors, 36% in those with middle or lower vaginal tumors, and 42% with whole-vaginal involvement. However, a larger series failed to note any difference in site of recurrence based on primary lesion location (3,35). In addition, lesions of the posterior wall have a worse prognosis than those involving other vaginal walls (10-year recurrence rates of 32% and 19%, respectively) (14), which probably reflect the greater difficulty of performing adequate brachytherapy procedures in this location.

The prognostic importance of lesion size has been controversial, with an adverse impact noted with increasing size on multivariate analysis in several series (14,16,39,117,121) contrary to Perez et al.'s (3,35) findings. In the Chyle et al. series (14), lesions measuring less than 5 cm in maximum diameter had a 20% ten-year local recurrence rate compared to 40% for those lesions larger than 5 cm. Similarly, in the Princess Margaret Hospital experience, tumors larger than 4 cm in diameter fared significantly worse than smaller lesions (16). In the Perez et al. series (35), stage was an important predictor of pelvic tumor control and 5-year disease-free survival, but the size of the tumor in stage I patients was not a significant prognostic factor. However, in stage IIA disease, lower pelvic tumor control and survival were noted with tumors larger than 4 cm. In stages IIB and III, tumor size was not a significant prognostic factor, probably related to the difficulty in assessing size and the fact that higher doses of RT were delivered for larger tumors. Stock et al. (21) reported that disease volume, a likely surrogate for stage or lesion size, adversely impacted survival as well as local control.

Age has also been reported as a significant prognostic factor with increasing age correlating with poorer survival (23,117,125). In the Urbanski et al. series (23), the 5-year

survival was 63.2% for patients below the age of 60 years compared with 25% for those over 60 years of age ($p < 0.001$). Similar findings were reported by Eddy et al. (113) and in the NCDB of the American College of Surgeons (5), showing better survival in younger patients (90% versus 30%, respectively). However, most of these series do not correct for death secondary to intercurrent disease in the elderly population. No statistical significance of age to survival was found in the series of Dixit et al. (114) and Perez et al. (35).

With regard to the histological type and grade, several series (16,123,126) have shown the histological grade to be an independent, significant predictor of survival. However, the histology of the tumor (SCC vs. other) has not been found to be a prognostic factor for survival among the patients with invasive tumors. Chyle et al. (14) noted a higher incidence of local recurrence in patients with adenocarcinoma compared with SCC (52% and 20%, respectively, at 10 years), as well as a higher incidence of distant metastases (48% and 10%, respectively), and lower 10-year survival rate (20% vs. 50%). A report by Frank et al. (63) compared outcome of patients with non-DES-associated adenocarcinoma of the vagina to that of patients with SCCs. They found a 5-year overall survival rate of 34% in the adenocarcinoma group compared to 58% for the patients with SCC ($p > 0.01$) (63).

An increased propensity for distant metastases to the lung and supraclavicular nodes has been reported in patients with CCA (37). Stage, tubulocystic pattern, size less than 3 cm, and depth of invasion less than 3 mm were all noted to be associated with superior survival (40).

Vaginal melanoma has a higher propensity for development of distant metastases, and affected patients do more poorly than patients with SCC. A review by Reid et al. of 115 vaginal melanoma patients noted that depth of invasion and size of lesion (>3 cm) adversely impacted survival, but stage did not, perhaps because it was known for only 42 of the 115 patients in the series. (31) Patients with malignant mesenchymal tumors of the vagina do worse than those with invasive SCC due to a higher propensity for development of local recurrence and distant metastases. Specific, adverse prognostic factors for vaginal sarcoma identified by Tavassoli and Norris (127) included infiltrative versus pushing borders, high mitotic rate of 5 or more mitoses per 10 HPFs, size greater than 3 cm in diameter, and cytological atypia. However, in a SEER analysis by Shah et al. (121), there was no difference in 5-year disease specific survival between all histological types, although vaginal melanoma was associated with an increased risk of mortality in their multivariate model (HR 1.51).

Overexpression of *HER2/neu* oncogenes in squamous cancer of the lower genital tract is a rare event that may be associated with aggressive biologic behavior (128). Waggoner et al. (129), in a group of 21 women with CCA of the vagina and cervix, observed a more favorable prognosis in gynecologic tumors with an overexpression of wild-type p53 protein than in tumors containing mutated *TP53* genes.

Lymph node metastasis at diagnosis portends a poor prognosis. However, this has not been extensively evaluated in vaginal cancer. The only report of outcome based on lymph node status is by Pingley et al. (130). They reported a 56% DFS for patients without lymph node involvement and 33% for those with metastatic lymphadenopathy at presentation.

In a recent series by Tran et al., which included only invasive SCC, prior hysterectomy as well as normal pretreatment/treatment hemoglobin levels were favorable prognostic factors on multivariate analysis in the treatment of vaginal cancer (119). In their review, it is recommended to consider transfusion with packed red blood cells to maintain normal hemoglobin levels as this approach has had some success in cervical cancer patients. Possible explanations for improved outcomes in women with previous hysterectomies included possible increased surveillance

with detecting vaginal cancer at an earlier stage, or simply less vaginal substrate for tumorigenesis to occur within (119). Chyle et al. (14) and Hellman et al. (117) also found that previous hysterectomy had more favorable outcome; however, this result did not hold up on multivariate analysis.

GENERAL MANAGEMENT: TREATMENT OPTIONS AND OUTCOME BY FIGO STAGES

Owing to its rarity, data concerning the natural history, prognostic factors, and treatment of vaginal carcinoma derive from small, single institutions, retrospective studies. Most of the currently available literature in terms of radiotherapeutic and surgical techniques refers to primary SCC of the vagina. It is important to recognize the complexity of the management of patients with carcinoma of the vagina and the need for an individualized approach after careful assessment by the gynecologic oncologist and radiation oncologist. With adequate therapy, the survival rates of patients with carcinoma of the vagina are comparable with those reported for carcinoma of the cervix, which range from 20% to 80% at 5 years, depending on stage of the disease (15,20,33,47,123,131). Perez et al. (4) noted a somewhat higher incidence of pelvic failures in patients with carcinoma of the vagina compared with 1,054 patients with invasive cervical carcinoma, although the differences are not statistically significant. Creasman et al. (5), in the NCDB report based on 4,885 patients with primary vaginal cancer, found the survival rate at 5 years to be 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stages III and IV. In addition, survival was better in the younger patients (90% vs. 30% in the older patients).

In most patients, the primary treatment modality is RT, as reported by the Society of Gynecologist Oncologists in practice guidelines published in 1998 (5). However, several surgical series have reported acceptable to excellent outcomes in well-selected patients, with survival rates after radical surgery for stage I disease ranging from 75% to 100% (5,13,24,33,39), although few studies directly compare the 2 treatment modalities. The SEER analysis by Shah et al. (121) showed that among women with stage I disease, those treated with RT only or RT and limited surgery or no treatment, had worse outcome than those treated with surgery alone (generally involving radical or exenterative procedures). However, only women with stage I disease who received no treatment had a statistically significant increased risk of mortality (HR 2.23; 95% CI, 1.01–5.03).

Local excision and partial and complete vaginectomy have given way to a more individualized approach that takes into consideration the patient's age, the extent of the lesion, and whether it is localized or multicentric. There is evidence that patients with CIS-VAIN and early stage I, primarily with a lesion located in the apex and upper third of the posterior and lateral walls of the vagina or distal third of the vagina, and highly selected women with stage II vaginal cancers can be successfully treated with surgery alone (13,21,24,39,132,133). These patients could be approached with radical hysterectomy, upper or partial vaginectomy, and pelvic lymphadenectomy, provided that adequate margins are obtained (13,15,21,24,33). If the margins are found to be close or positive after resection, adjuvant RT is recommended. In addition, surgery could be considered in younger patients with a desire to preserve ovarian function (134) and/or a functional vagina (21), patients with verrucous carcinoma (135), those with nonepithelial tumors, and patients with localized pelvic failures after radiation.

For the most part, surgical resection often requires a radical approach, resulting in urinary and fecal diversion in order to secure adequate margins (13,33). For those patients, definitive RT

has largely replaced surgery as primary therapeutic modality, in order to maximize cure and improve quality of life, with isolated central failures offered exenteration (33). Even in patients with early stage I invasive tumors involving the middle or upper third of the vagina, surgical treatment requires radical vaginectomy and pelvic lymph node dissection. Frequently the patient has undergone previous hysterectomy, but if the uterus is still present, concurrent hysterectomy may be necessary to achieve adequate margins. Lindeque (305) pointed out that most tumors require removal of the full length of the vagina, although in localized lesions a partial colectomy may be performed. Although radical surgery in the past precluded vaginal function, this has improved significantly by the use of split-thickness grafts and myocutaneous flap (136). Gracilis myocutaneous flaps and rectus abdominis myocutaneous flaps have been commonly used for neovaginal reconstruction following radical pelvic surgery, with superior results noted in those undergoing rectus abdominis reconstruction (136).

Given the potentially devastating functional results often associated with radical surgery, definitive RT has largely replaced surgery as the primary therapeutic modality in patients with vaginal cancer, in order to maximize cure and improve quality of life. Furthermore, most patients are elderly, and a radical surgical approach is often not feasible. Despite the acceptance of RT as the treatment of choice for this disease, the optimal approach for each stage is not well defined in the literature. A combination of limited surgery and RT has been suggested to improve outcome, although the complication rates may increase (137). Frank et al. (48) suggest that radiation treatment be individualized with the optimal treatment approach selected according to the tumor size, tumor site, extent of disease, and response to initial RT. Intracavitary and interstitial irradiation is used in small superficial stage I disease. External beam RT (EBRT) in combination with intracavitary (ICB), and/or interstitial (ITB) brachytherapy is generally used for more extensive stage I-II disease. Data regarding the use of cytotoxic therapy in vaginal carcinomas are based on underpowered phase II trials of various monotherapies or extrapolated from SCC of the cervix, which has a similar biology.

FIGO Stage 0: Vaginal Intraepithelial Neoplasia—Carcinoma *In Situ*

VAIN has been approached both surgically and medically by multiple investigators. Treatment options range from partial or complete vaginectomy to more conservative approaches such as local excision, electrocoagulation, laser vaporization, topical 5% fluorouracil (5-FU) administration, or ICB. For patients in whom invasive disease cannot be ruled out, as well as for those who fail conservative therapy, surgical resection remains the treatment of choice. Overall, the reported control rates are very similar among the different approaches, ranging from 48% to 100% for laser (138–140), 52% to 100% for colectomy (5,132,133,141), 75% to 100% for topical 5-FU (142–145), and 83% to 100% for RT (14,16,131), (Table 20.3) (5,14,16,35,131–133,140–145). The degree of VAIN and the age and general health of the patient are important treatment considerations. A therapy appropriate for CIS in a woman with good performance status and many anticipated years of life expectancy may not be appropriate for a woman with multiple comorbidities who may succumb to one of her other illnesses before the CIS would be expected to progress to invasive carcinoma.

The anatomic constraints posed by the location of the vagina with the close proximity of the bladder and rectum led to the use of the CO₂ laser as a relatively noninvasive surgical approach (139,140). Data published by Hoffman et al. (133), who performed upper colectomy in 32 patients, of whom 31 had

Table 20.3 VAIN—Carcinoma *In Situ*: Treatment Approach and Results

Treatment Modality, Author(s)	No. of Patients	Comments	Outcome Local Control
Laser Therapy			
Julian et al. (140)	10	Used to effect colpectomy	80%
Hoffman et al. (139)	26	3 of 11 failures had invasive disease Recommended excision. Not ideal	58%
Topical 5-FU			
Woodruff et al. (145)	9	1%–2% 5-FU q month	88%
Piver et al. (144)	8	20% 5-FU bid × 5 d Could use 5% or 10%	75%
Petrilli et al. (143)	15	5% 5-FU bid × 5 d Repeat in 12 wk	80%
Krebs (142)	31	One-third applicator q wk × 10 wk	81%
Surgical Excision			
Creasman et al. (NCDB) (5)	23		96%
Fanning et al. (132)	15	Used LEEP, 1 patient had cancer	100%
Robinson et al. (141)	46	CUSA—29 primaries CUSA—17 recurrent	66% 52%
Hoffman et al. (133)	32	28% invasive cancer out of 23 with VAIN	83%
Irradiation			
Chyle et al. (14)	37		83%
Kirkbride et al. (16)	14		100%

5-FU, 5-fluorouracil; bid, twice a day; CUSA, Cavitron ultrasonic aspirator; LEEP, loop electrosurgical excision procedure; NCDB, National Cancer Data Base.

undergone prior hysterectomy and 14 prior therapy for VAIN, and found a 28% risk of invasive disease, in addition to reports of invasive disease in the laser failures, and in patients who had undergone upper colpectomy for presumed VAIN, prompted some to begin to use the laser to effect colpectomy (140). Later series have used novel approaches with the Cavitron ultrasonic aspirator (CUSA) (141) to effect partial colpectomy with satisfactory results, at least in the reporting investigator's hands. In a series of 52 patients reported by Diakomanolis et al., in which 28 underwent laser and 24 had partial colpectomy, results were found to be operator dependent, but they favored partial colpectomy for unifocal disease and laser ablation for multifocal disease (138). Overall, the control rates following laser vaporization range from 58% to 100% (139,140). Patients most likely to fail after vaporization are those with anatomic distortion caused by scarring (133). In general, patient acceptance is high and scarring is minimal (146).

Even though partial colpectomy has many advocates for focal VAIN without any prior history of pelvic RT, patients who had received prior pelvic RT for other gynecologic malignancies, wherein partial colpectomy would have high risk of fistula formation, may benefit from a medical approach with topical application of 5-FU. This creates a desquamation of the vaginal squamous epithelium, which later reepithelializes with presumably normal cells. Multiple schedules have been suggested since the first use of 5-FU, including monthly, daily, twice a

day, and weekly administrations, with control rates ranging from 75% to 88% (142,144,145,147). However, we prefer the schedule suggested by Krebs et al. of one-third applicator weekly for 10 weeks (142). It is important that the perineal skin be protected with a topical ointment such as zinc oxide to prevent painful vulvar erosions regardless of which 5-FU application schedule is chosen. More recently, investigators have demonstrated the feasibility and likely efficacy of Imiquimod (Aldara®) in the treatment of VAIN, although large series remain to be performed (148). In the study by Haidopoulos et al., 6 out of 7 patients with high-grade dysplasia (VIN 2–3) regressed to either no evidence of dysplasia or VIN 1 following Imiquimod treatment (148). Application of 0.25 g of Imiquimod 5% intravaginally once weekly for 3 weeks was effective and well tolerated. Larger studies are required, but this regimen appears to be promising, with a simpler dosing regimen, and lower toxicity when compared to 5-FU (148).

Partial or total vaginectomy has been considered by many to be an acceptable treatment for VAIN (127). However, one of its main drawbacks is shortening or stenosis of the vagina, frequently with poor functional results. Hoffman et al. (133) reported a 17% recurrence rate in a series of 32 patients with CIS of the vagina who underwent upper vaginectomy. In this series, 44% had received prior therapy, including laser vaporization, or topical 5-FU and local excision. Nine patients (28%) were found to have invasive cancer upon final pathologic examination. Four

of 9 patients with invasive carcinoma showing more than 3.5-mm infiltration were treated subsequently with RT, 3 of these patients remained free of disease. Of the 5 patients with less than 2 mm invasion, 1 received RT for local recurrence, and the remaining 4 patients were without disease after surgery alone. Overall, 5 of 9 patients with microinvasive carcinoma required RT in addition to surgery, and only 72% of all patients treated with surgery remained free of disease at last follow-up. Of 23 patients with VAIN 3, 19 (83%) remained without evidence of recurrence at a mean follow-up of 38 months. Hoffman et al. (133) advocated upper vaginectomy with 1 cm margins when there were concerns about possible invasion, and when the lesion was confined to the upper one-third or one-half of the vagina. To minimize postoperative stenosis, they (133) recommend not closing the mucosa, using a dilator with estrogenic vaginal cream, and consideration of a skin graft. Prior RT is probably a contraindication to vaginectomy owing to significantly increased morbidity. Control rates of 66% to 100% following partial colectomy effected with a traditional surgical approach (133,149), with CUSA (141), or with the loop electrosurgical excision procedure (LEEP) (132) have been achieved.

Radiation therapy has a long history of documented efficacy with control rates ranging between 80% and 100%, and a significantly better therapeutic ratio than other modalities (14,16,18,35,47,150). Using conventional low-dose-rate (LDR) ICB techniques, the entire vaginal mucosa should receive between 50 and 60 Gy, given the high incidence of multicentricity; the area of involvement should receive 70 to 80 Gy, in 1 or 2 implants, prescribed to the mucosal surface (131). Higher doses may cause significant vaginal fibrosis and stenosis. Perez et al. reported only 1 distal local failure in the 20 patients treated for CIS (131). Pelvic recurrences or distant failures have not been observed in the absence of invasive component, after ICB (44,131,151).

There have been some reports in the literature regarding the use of high-dose-rate (HDR) ICB for patients with VAIN 3. Ogino et al. (152) reported 6 patients treated with HDR to a mean dose of 23.3 Gy (range, 15 to 30 Gy), none of whom developed recurrent disease. Limited rectal bleeding and moderate to severe vaginal mucosa reactions were noted in patients treated to the entire length of the vagina. MacLeod et al. (153) reported on 14 patients with VAIN 3 treated with HDR-ICB to a dose of 34 to 45 Gy in 4.5- to 8.5-Gy fractions. With a median duration of follow-up of 46 months, 1 patient had persistent tumor and another showed progression of tumor with an overall local control of 78.5%; 2 patients developed grade 3 vaginal toxicity. Mock et al. (154) reported 100% recurrence-free survival in 6 patients with CIS treated with HDR-ICB. At the present time, no definite conclusions can be drawn from the limited data published in the literature regarding the use of HDR-ICB. Based on the excellent local control and functional results obtained with LDR-ICB, this remains, in our opinion, the treatment of choice when definitive RT is used.

Estrogen therapy should be considered in women who are postmenopausal or have undergone RT, provided the possibility of invasive disease has been eliminated. The effect of irradiation on ovarian function, as well as occasional fibrosis of the vaginal vault, makes this treatment currently unacceptable except in cases resistant to conservative therapy.

Invasive SCC

Surgical Approach and Outcomes

In general, SCC of the vagina has been treated with RT. However, several surgical series have reported acceptable to excellent outcomes in well-selected patients, with survival rates

after radical surgery for stage I disease ranging from 75% to 100% (5,14,21,24,33,39). Cases in which surgery may be the preferred treatment include selected stage I-II patients, with lesions at the apex and upper third of the posterior or lateral vagina that could be approached with radical hysterectomy, upper vaginectomy, and pelvic lymphadenectomy providing adequate margins (10,12,18,21) and very superficial lesions that may be removed with wide local excision. Lesions in the lower third of the vagina would require vulvovaginectomy in addition to dissection of inguinofemoral nodes or even exenteration to achieve negative margins (13,15,21,33). If the margins are found to be close or positive after resection, adjuvant RT is recommended. However, for lesions at other sites, and those cases requiring more extensive resection, definitive RT is the treatment of choice since it offers excellent results (4), with isolated central failures postirradiation being offered exenteration (33).

Creasman et al., in a review of the NCDB for cancers of the vagina, noted superior survival in those patients undergoing surgery (5). However, they and Tjalma et al. (39) recognized that there may be bias in surgical series, such that younger, healthier patients with better performance status are more likely to be offered radical surgery, whereas older patients with multiple comorbid medical conditions are offered RT.

Ball and Berman's series (13) included 58 patients: 27 stage I and 18 stage II disease. Twenty-seven patients were managed primarily with surgery, with an overall 78% 5-year survival rate, 84% in patients with stage I, and a 63% rate in those with stage II disease, which is comparable to the results reported by Perez et al. in their RT series (4,35). Rubin et al. (33) reported 75 cases of vaginal cancer: 14 patients with stage I and 35 patients with stage II. RT was the primary modality used in this series; however, 8 patients (5 with stage I and 3 with stage II) underwent primary surgery with curative intent. Six of these 8 patients survived 5 years, and the local control rate for stage I patients was 80%. However, only 1 patient with stage II was a long-term survivor. This surgical outcome compares unfavorably with the remaining patients in whom RT was the primary modality. In general, patients with lesions that could be encompassed by radical vulvovaginectomy with or without hysterectomy did better than those requiring exenteration. Rubin et al. (33) advocated that exenteration should be reserved for those with central failure after RT, or as primary therapy in those with disease not fixed to the bone. Davis et al. (24) reported on 52 patients with cancer of the vagina treated with surgery alone in a series that included 89 cases. In this nonrandomized series, an 85% 5-year survival rate was achieved in stage I patients compared to 65% in those treated with RT (24). Of 45 patients with stage II disease, 49% survived after surgery, 50% after RT, and 69% after surgery and RT.

The Peters et al. series (110) included 86 vaginal carcinomas, with an overall survival rate of 56%. Most were treated with RT. However, 12 highly selected patients had surgery, with a 75% survival rate. The investigators suggested that vaginectomy with radical hysterectomy, if the uterus was still in place, should be limited to those with superficial disease because the closeness of the bladder and rectum limited the true radicality of surgical approaches. Gallup et al. (15) reported 28 cases, of which 57% were stage I to II lesions (only 3 patients had stage II), and of these, 83% survived. Most patients in this series received RT; however, all 3 patients with stage I disease who were treated with surgery survived. Extent of surgery and median follow-up were not stated.

In the largest single-institution series reported to date by Stock et al. (21), of 100 patients with carcinoma of the vagina (including 85 with SCC), a 47% 5-year survival rate was achieved. In this series, 40 patients were treated with surgery alone, 47 with radiation alone, and 13 with combination

therapy. Overall, 5-year survival was 47%. Survival for stage I patients was 56% when treated with surgery versus 80% for those who received RT, whereas for stage II patients, the survival rates were 68% and 31% after surgery and RT, respectively (21). The investigators acknowledged that the apparent surgical superiority for stage II patients may have been due to selection bias in that those treated with RT alone were more likely to have had stage IIB disease with extensive paracolpos involvement, and those with lesser involvement were preferentially offered surgery. Stock advocated RT for stage II patients with extensive paracolpos. Stock et al. concluded that for upper-third vault lesions, radical hysterectomy and pelvic lymphadenectomy with upper vaginectomy should be offered to those with stage I lesions, with a consideration for wide local excisions, and postoperative RT for patients with small lesions. If there was extension to the paracolpos, RT should be recommended; however, in very well-selected patients, there might be a role for surgery (21).

Tjalma et al. reported on 55 cases of SCC of the vagina, including 27 cases with stage I and 12 with stage II disease, with a median follow-up of 45 months (39). Of the 27 cases with stage I disease, 26 underwent surgery, and 4 of them received some form of postoperative RT. A 91% 5-year survival rate was achieved for stage I disease. Surgery was a part of the primary management for 6 of the 12 patients with stage II disease. In the multivariate analysis, age and lesion size were the only prognostic factors. Tjalma et al. concluded that surgery should be considered part of the therapeutic approach for stage I and minimal stage II disease (39). However, as Stock et al. suggested (21), and later Creasman et al. (5) and Tjalma et al. (39) concurred, such apparent improvement in small surgical series may be secondary to a selection bias such as patients with better performance status and smaller lesions are selected for surgery, whereas older patients with more comorbid medical conditions and larger stage I to II lesions undergo RT.

While several series have reported on primary surgical approaches, including exenteration for patients with advanced stage III–IV SCC, achieving control rates as high as 50% for highly selected patients (13,15,21,33), the number of patients treated in any single series is so small that in modern practice, primary exenteration for advanced disease would not be recommended as the preferred approach (137). Therefore, advanced-stage patients should receive definitive RT, probably in combination with concurrent chemotherapy, although the role of combined modality therapy is unknown.

With regard to the surgical technique, if a complete vaginectomy is to be undertaken, most experts have suggested a combined abdominoperineal approach, with the perineal incision in the pubocervicovesical fascia made beneath the urethra and above the rectum so as to avoid the hemorrhoidal plexus. Some have suggested that the perineal incision can be made before or after the abdominal incision to perform the radical abdominal resection. However, we would favor performing the abdominal incision, first mobilizing the bladder, urethra, and rectum down to the perineum, and dividing the paracolpos at the side wall, mobilizing the ureters, and harvesting the nodes such that if unresectable disease is found, the patient would be spared a perineal incision. Given the large defect that is left after surgical resection, placement of a gracilis myocutaneous flap allows not only coverage of the defect, but may serve as a neovagina in the sexually active woman (155,156). Alternatively, 2 new techniques have been described with excellent results. Vaginal reconstruction can be performed with the use of vicryl mesh combined with a pedicle omental grafter with a deep inferior epigastric perforator flap. Both techniques have been shown to be effective, and when performed at the time of pelvic exenteration, carry the additional benefit of avoiding an additional surgical incision, as required for creation of a

gracilis flap. Long-term follow-up has been favorable for the former, while only preliminary data is available for the latter (157,158).

Radiation Approach: Outcomes

Stage I. In patients with stage I lesions, usually 0.5 to 1 cm thick, that may involve 1 or more vaginal walls, it is important to individualize radiation therapy techniques to obtain optimal functional results. Most investigators emphasize that brachytherapy alone is adequate for superficial stage I patients with 95% to 100% local control rates when using low-dose-rate (LDR) ICB and ITB techniques (4,18,110,123).

Superficial lesions with less than 3 mm invasion can be adequately treated with ICB alone, using afterloading vaginal cylinders. The entire length of the vagina is generally treated to a mucosal dose of 60 Gy, and an additional mucosal dose of 20 to 30 Gy is delivered to the area of tumor involvement (131). Mucosal doses of 80 to 100 Gy are typically delivered, depending on the diameter of the cylinders, when prescribing 65 to 70 Gy to the tumor area, at 0.5 cm depth beyond the vaginal surface (131). For lesions thicker than 0.5 cm at the time of implantation, it is advisable to combine ICB and ITB with a single-plane implant to increase the depth dose and limit excessive irradiation to the vaginal mucosa. With LDR-ICB a dose of 60 to 65 Gy is delivered to the entire vaginal mucosa; the dose to 0.5 cm depth from the ICB should be calculated; an additional 15 to 20 Gy at a depth of 0.5 cm beyond the plane of the implant will be delivered with the ITB such that the base of the tumor receives between 65 and 70 Gy, with the involved vaginal mucosa receiving an estimated 80 to 100 Gy. The proximal and distal vaginal mucosal doses should be limited to 140 and 98 Gy, respectively (131).

There are no well-established criteria regarding the use of external beam RT (EBRT) in patients with stage I disease. Perez et al. (4,35) did not find a significant correlation between the technique of irradiation used and the probability of local or pelvic recurrence, probably since the treatment technique varied based on tumor-related factors. There is general consensus that EBRT is advisable for larger, more infiltrating or poorly differentiated tumors that may have a higher risk of lymph node metastasis. The whole pelvis is treated with 10 to 20 Gy; an additional parametrial dose should be delivered with a midline block (5 half-value layer [HVL]) to give a total of 45 to 50 Gy to the parametria and pelvic side walls (4,35). Chyle et al. (14) recommended EBRT in addition to brachytherapy for stage I disease to cover at least the paravaginal nodes, and, in larger lesions, to cover the external and internal iliac nodes. Ninety-five percent to 100% local control has been achieved with intracavitary and interstitial techniques, with 5-year survival for patients with stage I disease treated with RT alone ranging from 70% to 95% (Table 20.4) (4,18,21,23,48,123).

Stage II. Patients with stage IIA tumors have more advanced paravaginal disease without extensive parametrial infiltration. These patients are uniformly treated with EBRT followed by ICB and/or ITB. Perez et al. (35) showed that in stage IIA, the local tumor control was 70% (37/53) in patients receiving brachytherapy combined with EBRT, compared with 40% (4/10) in patients treated with either brachytherapy or EBRT alone. Generally, the whole pelvis receives 45 Gy followed by an additional boost using a combination of LDR-ICB or LDR-ITB in order to deliver a minimum of 30 to 35 Gy 0.5 cm beyond the deep margin of the tumor (in addition to the whole pelvis dose, to a total tumor dose of 75 to 80 Gy). Double-plane or volume implants may be necessary for more extensive disease. The superiority of the combination of EBRT and brachytherapy over EBRT or brachytherapy alone has been shown as well in other series (14,21,122).

^aFour patients received adjuvant irradiation.

Patients with stage IIB, with more extensive parametrial infiltration, will receive 40 to 50 Gy whole pelvis and 55 to 60 Gy total parametrial dose (with midline shielding). An additional boost of 30 to 35 Gy will be given with LDR interstitial and intracavitary brachytherapy, to deliver a total tumor dose of 75 to 80 Gy to the vaginal tumor (14,23,35,122). In patients with parametrial infiltration, a “boost” with EBRT and/or an interstitial implant is advisable to deliver a minimum tumor dose of 70 to 75 Gy and 55 to 60 Gy to the pelvic side wall. The pelvic side wall dose should be kept below 60 Gy (including the contributions of EBRT and brachytherapy) (35). Patients with lesions limited to the upper third of the vagina can be treated with an intrauterine tandem and vaginal ovoids or cylinders. The local-regional control in patients with stage IIB in the Perez et al. series (35) was also superior with combined EBRT and brachytherapy (61% vs. 50%, respectively).

The 5-year survival for patients with stage II disease treated with RT alone ranges between 35% and 70% for stage IIA, and 35% and 60% for stage IIB (14,21,35). The results of several series published in the literature using different treatment approaches for stage I and II vaginal cancer are shown in Table 20.4 (5,13,14,16,21–24,33,35,39,48,117,119,120,123,159–162).

Stage III–IVA. Generally, patients with stage III and IVA disease will receive 45 to 50 Gy EBRT to the pelvis, and in some cases, additional parametrial dose with midline shielding to deliver up to 60 Gy to the pelvic side walls. Ideally, ITB brachytherapy boost is performed, if technically feasible, to deliver a minimum tumor dose of 75 to 80 Gy. If brachytherapy is not feasible, a shrinking-field technique can be used, with fields defined using the 3-dimensional treatment planning capabilities to deliver a tumor dose around 65 to 70 Gy. An alternative approach is intensity modulated RT (IMRT) using multiple beams of varying intensity that conform the high-dose region to the shape of the target tissues, with more adequate sparing of the surrounding normal tissues, primarily the bladder, rectum, and small bowel (163,164).

Boronow et al. (137) proposed an alternative to exenterative procedure for locally advanced vulvovaginal carcinoma, using RT to treat the pelvic disease and a radical vulvectomy with bilateral inguinal node dissection to treat the vulvar extension of the tumor. External irradiation to the pelvis and inguinal nodes consisted of 45 to 50 Gy, combined with LDR intracavitary insertions to deliver maximal doses of 80 to 85 Gy to the vaginal mucosa with both modalities. The overall cure rate for patients with stage III disease is 30% to 50%.

Stage IVA includes patients with rectal or bladder mucosa involvement, or in most series, positive inguinal nodes. Although some patients with stage IVA disease are curable, many patients are treated palliatively with EBRT only. Pelvic exenteration can also be curative in highly selected stage IV patients with small-volume central disease. Table 20.5 (5,13,14,16,21,23,33,35,48,119,120,123,159,161,162) shows the treatment results with different therapeutic modalities, including 4 series that reported the use of primary surgery in highly selected patients with advanced disease. However, each of these series reported a far greater number of patients with similar stage disease treated with RT, which represents the preferred approach in contemporary practice (4,47).

Radiation Therapy Techniques

External Beam Radiotherapy

EBRT is advisable in patients with deeply infiltrating or poorly differentiated stage I lesions and in all patients with stages II to IVA disease. The treatment is generally delivered using opposed anterior and posterior fields (AP/PA). The pelvis receives between 20 and 45 Gy, depending on the stage of the disease.

^aTwenty patients with St III–IV were treated with chemotherapy (5-FU ± mitomycin C) and radiotherapy.

This will be followed, in some cases, by bilateral pelvic sidewall boosts from 50 to 55 Gy. High-energy photons (≥ 10 MV) are usually preferred. CT simulation is highly encouraged since it allows a more accurate delineation of the regional lymph node areas, rather than relying on pelvic bony anatomy (165). Treatment portals cover at least the true pelvis with 1.5- to 2.0-cm margin beyond the pelvic rim. Superiorly, the field extends to either L4–5 or L5–S1 to cover the pelvic lymph nodes up to the common iliacs, and extends distally to the introitus to include the entire vagina. The distal margin of the tumor should be identified with a radiopaque marker or bead at the time of the simulation. Lateral fields, if used, should extend anteriorly to adequately include the external iliac nodes, anterior to the pubic symphysis, and at least to the junction of S2–3 posteriorly to adequately cover the presacral nodes (Fig. 20.6).

In patients with tumors involving the middle and lower vagina with clinically negative groins, the bilateral inguinofemoral lymph node regions should be treated electively to 45 to 50 Gy (35). Planning CT is recommended to adequately determine the depth of the inguinofemoral nodes. In patients with distal vaginal lesions it is often necessary to treat the vulva in order to achieve adequate tumor coverage, in which case the patient should be placed in open-leg position to reduce the vulvar skin reaction (48).

A number of techniques have been used to treat the areas at risk without overtreating the femoral necks. Some of the most commonly used techniques include the use of unequal loading (2:1, AP/PA), a combination of low- and high-energy photons (4 to 6 MV, AP; and 15 to 18 MV, PA), or equally weighted beams with a transmission block in the central AP field, utilizing small AP photon or electron beams to deliver a daily boost to the inguinofemoral nodes (166). A technique has been developed and implemented at Indiana University that uses a narrow PA field to treat the pelvis and a wider AP field encompassing the pelvis and inguinofemoral nodes, with daily AP photon boost to the inguinal nodes being delivered using the asymmetric collimator jaws (167). Advantages of this technique include simplicity of setup and treatment (single isocenter, no need for transmission block), dose homogeneity, reduced dose to the femoral necks, low potential risk of nodal underdose, and elimination of dosimetric difficulties inherent in electron boosts (Fig. 20.7).

The above technique was initially set up and planned using a conventional simulator. With the advent of more modern CT based simulation and 3D treatment planning software, the technique described above is being replaced by a similar technique described by Moran et al. (168) with some modifications. In their technique called modified segmental boost technique (MSBT), Moran et al. (168) use CT simulation and 3D treatment planning software that incorporate multileaf collimators (MLC's) to shape the desired fields. Relevant anatomic areas such as femoral vessels, involved nodes etc. are outlined on the CT scan to help create the appropriate field borders. The field arrangements are similar to the Indiana University technique including a wide AP photon field, a narrow PA pelvic field, and a bilateral (or unilateral) inguinal boost field(s). The inguinal fields are angled slightly to align with the divergence of the PA field and are shaped using MLC's. They found this technique significantly improved homogeneity throughout the treatment volume in comparison to other traditional techniques (168).

In patients with clinically palpable inguinal nodes, additional doses of 15 to 20 Gy (calculated at a depth determined by CT scan) are necessary with reduced portals. This is generally achieved by using low-energy photons or electron beam (12–18 MeV). For patients with positive pelvic nodes, or those patients with advanced disease not amenable to interstitial implant, additional boost to the areas of gross disease, as defined by CT scan, should be given using conformal therapy to deliver a total dose between 65 to 70 Gy, when feasible, with high-energy photons.

Intensity modulated radiation therapy (IMRT) is another potential therapeutic option in pelvic tumors that require the treatment of the inguinofemoral region as well as delivering higher doses to the gross disease while reducing the dose to the bladder and rectum (Fig. 20.8) (163,164,168–172). It is postulated that the use of IMRT may reduce acute and long-term toxicity by minimizing the dose to organs at risk (OAR). This is a topic of current investigation in a phase II RTOG trial (05–29), in which IMRT to the pelvic and inguinal nodes is being combined with chemotherapy for anal cancer in a multi-institutional setting. Moran et al. (168) performed a dosimetric comparison of the MSBT technique to IMRT for treatment of pelvic/inguinal nodes in variety of patients, including those with the diagnoses of primary vaginal cancers (168). The doses to the bladder, rectum, small bowel, and bone marrow were higher using the MSBT technique compared to IMRT plan; however, the treatment planning process (including contouring) was 40 minutes for the MSBT plan compared to approximately 6 hours for the IMRT plan (168). At this time there is not sufficient data on outcomes to routinely recommend the use of IMRT for the treatment of primary vaginal cancer when the inguinofemoral nodes must be irradiated. Certain clinical scenarios may warrant the use of IMRT, such as those patients who require doses greater than 50 Gy to the pelvis or inguinofemoral region or

FIGURE 20.6. Proximal third vaginal cancer; invasive squamous cell carcinoma, with mid-third of the vagina squamous cell carcinoma *in situ*, without involvement of inguino-femoral nodes. when radiation must be delivered to an area that has previously been irradiated.

Independently of the technique to be used, it is important to keep in mind that the overall treatment time (7 to 9 weeks) has been found to be a significant treatment factor predicting tumor control (130,150), although this has not been universally recognized (35).

Low-Dose-Rate Intracavitary Brachytherapy

VAIN and small T1 lesions with less than a 0.5-cm depth can be adequately treated with intracavitary brachytherapy (ICB)

alone. Low-dose-rate (LDR)-ICB is performed using vaginal cylinders such as Burnett, Bloedorn, Delclos (173), or MIRALVA (Nucletron Veenendaal, the Netherlands) (174) loaded with cesium 137 (^{137}Cs) radioactive sources. Choo et al. (175) evaluated the depth distribution of lymphatics lying beneath the mucosal surface of the vagina in 31 patients who underwent full-thickness vaginal biopsy or resection for benign or malignant lesions. In their series, 95% of vaginal lymphatic channels were located within a 3 mm depth from the vaginal surface, confirming the adequacy of prescribing the dose to a depth of 5 mm for superficially invasive lesions (173).

FIGURE 20.7. Vaginal cancer with distal third vaginal involvement, squamous cell carcinoma. Technique for pelvic and inguinofemoral nodal irradiation. **A:** Digital reconstructed radiographs. AP field intended to treat pelvis and groins; PA field intended to treat the pelvis only, in order to decrease the dose to the femoral heads; small AP photon field for additional daily boost to the inguinofemoral nodes. **B:** Axial, sagittal, and coronal isodose distributions.

Delclos afterloading vaginal cylinders have a central hollow metallic cylinder in which the sources are placed, and plastic rings of varying diameter (2.5 to 4 cm), 2.5 cm in length, which are inserted over the cylinder. Domed cylinders are used to irradiate the vaginal cuff homogeneously, when indicated. Delclos recommended a short ^{137}Cs source to be used at the top to obtain a uniform dose around the dome, because a lower dose occurs at the end of the linear cesium source (173). Some cylinders have a lead shielding to protect selected portions of the vagina,

the bladder, and/or the rectum. It is recommended that the largest possible diameter that can be comfortably accommodated by the patient should be used to improve the ratio of mucosa to tumor dose, and to eliminate vaginal rugations. The cylinders can be mounted in the vaginal component of an intrauterine tandem, or along the stem of a dome cylinder. Before the cylinders are mounted over the vaginal component of an intrauterine tandem, this is inserted into the uterus (when present) and the cylinders are fitted along the protruding tandem. To minimize

FIGURE 20.8. **A:** Axial dose distribution intensity-modulated radiation therapy plan for vaginal cancer. **B:** Sagittal dose distribution IMRT plan for vaginal cancer. **C:** Coronal dose distribution IMRT plan for vaginal cancer. **D:** Beam arrangement IMRT plan for vaginal cancer.

the rotation of the tandem, a flat, round flange with keel is placed below the last cylinder and is kept in position with some packing if required. In general, the vulva is sutured-closed with praline or silk for the duration of the implant in order to secure the position of the applicators (Fig. 20.9). In general, the vulva is sutured closed for the duration of the implant in order to secure the position of the applicators.

In patients with upper vagina lesions with less than a 0.5 cm depth of invasion, vaginal colpostats alone (after hysterectomy) or in combination with intrauterine tandem, loaded with ^{137}Cs sources similar to that used in treatment of cervical cancer, can be used to treat the proximal vagina to a minimum dose of 65 to 70 Gy, estimated to 0.5 cm depth, including the contribution of EBRT if given. When indicated, the remainder of the vagina can be treated by performing a subsequent implant using vaginal cylinders (generally 50 to 60 Gy prescribed to the vaginal surface). It is important to avoid the placement of a protruding source over the vulva, with the subsequent increased risk of complications. When appropriate dose specification points are chosen, a very uniform dose distribution over the entire length of the vagina can be obtained. Perez et al. and Slessinger et al. (174) designed and constructed a vaginal applicator, MIRALVA, which incorporates 2 ovoid sources and a central tandem that can be used to treat the entire vagina (alone or in combination with the uterine cervix). The applicator has vaginal apex caps and additional cylinder sleeves to allow for increased dimensions. A tandem in the uterus can be used if clinically indicated, using standard loadings, depending on the depth of the uterus. The vaginal cylinder or uterine tandem never carries an active source at the level of the ovoids to prevent excessive doses to the bladder or rectum. The use of LDR remote control afterloading

technology allows the reduction of radiation exposure to hospital personnel and optimization of the isodose distribution.

High-Dose-Rate Intracavitary Brachytherapy

The International Commission of Radiation Units (ICRU) defines HDR brachytherapy as exceeding 12 Gy/hour (35). High-dose-rate intracavitary brachytherapy (HDR-ICB) is typically performed with a 10 Ci single iridium-192 (^{192}Ir) source (Micro-Selectron HDR, Nucletron). The applicators are similar to those described for LDR.

Limited information regarding HDR-ICB in the treatment of primary carcinoma of the vagina is available (22,154,176–180). Fewer patients have been treated compared with LDR-ICB, follow-up for most series is short, publication bias is likely, and there is no agreement on treatment regimen. With HDR there is a need to adjust the total dose and additional fractionation is necessary, compared with LDR brachytherapy, because of the biologically equivalent dose considerations. Generally, the number of insertions ranges from 1 to 6 (median, 3), with the dose per fraction ranging from 300 to 800 cGy (median, 700 cGy).

HDR-ITB has also been reported by Kushner et al. (177); in this report, the Syed Template Applicators were used. Newer HDR compatible interstitial systems are available including the M.A.C. (Mick-Alektiar-Cohen) HDR-GYN Contour Template, compatible with ultrasound stabilizing devices, and the Miami Multi-Channel Vaginal Applicator (Mick Radio-Nuclear Instruments Inc., Mount Vernon, NY) (Fig. 20.10).

Stock et al. (22) described results in 15 patients with carcinoma of the vagina treated with HDR brachytherapy; dose per fraction ranged from 3 to 8 Gy, with a median dose of

FIGURE 20.9. AP (A) and lateral views (B) of vaginal cylinders only. AP (C) and lateral views (D) of intrauterine tandem and vaginal cylinders.

7 Gy, for a total median dose of 21 Gy. The median interval between fractions was 2 weeks. Brachytherapy was combined with EBRT (30 to 63 Gy, with a median dose of 42 Gy, 1.8 to 2.92 Gy per fraction). The median total tumor dose from both components was 63 Gy. The 5-year actuarial survival rate was 50% with brachytherapy, compared with 9% in the EBRT-alone patients ($p < 0.001$), although a larger percentage of stage IV lesions (36%) were in the EBRT-alone group than in the brachytherapy group (5%). Local tumor control rates were 50% for

stage I, 47% for stage II, and 40% for stage III. Survival closely paralleled tumor control. There was no significant difference in outcome in the LDR or HDR groups. Acceptable morbidity of therapy was noted for all 49 patients, but no comment was made comparing LDR with HDR (22).

Nanavati et al. (178) reported 13 patients with primary vaginal cancer (5 St I, 4 St IIA and 4 St IIB) treated with external beam RT (45 Gy) and HDR-ICB (20–28 Gy in 3–4 fractions, calculated at 0.5 cm from the surface of the applicator). All

FIGURE 20.10. A: M.A.C. HDR-GYN Contour Template. B: HDR CT Miami Multi-Channel Vaginal Applicator.

Source: Reprinted with permission from Mick Radio-Nuclear Instruments, Inc.

13 patients had a complete response, and local control was achieved in 92% of the patients with a median follow-up of only 2.6 years (range 0.7 to 5.2 years). Originally the planned dose was 2100 cGy in 3 fractions, 700 cGy/fraction, but because of reports of decreased complications with increased fractionation, the planned dose was changed to 2000 cGy in 4 equal fractions. The investigators did not observe any acute or chronic intestinal or bladder grade 3 or 4 toxicity. However, moderate to severe vaginal stenosis occurred in 46% of the patients. They recognize that “late-occurring toxicity could be missed at a medium follow-up of 2.6 years” (178).

Kucera et al. (176) reported on 190 patients with invasive carcinoma of the vagina. Eighty were treated with intracavitary HDR-ICB with or without EBRT. These patients are compared with a historical group of 110 patients treated with intracavitary LDR brachytherapy with or without EBRT. No significant differences were found for stages, tumor grade, or location between the 2 groups. The crude 5-year survival rates for all patients were 41% in the LDR group, 81% in stage I, and 43% in stage II. Overall actuarial 3-year survival and disease-specific survival rates for all patients in the HDR series were 51% and 66%, respectively. Disease-specific 3-year survival rates were 83% in stage I and 66% in stage II. There were no significant differences in local and distant recurrences between the treatment modalities. Complications analysis showed no significant differences between the HDR and LDR series. Similar results were published by Mock et al. (154) in 86 patients treated with HDR-ICB alone or in combination with EBRT with fairly good toxicity profile. However, Kushner et al. (177) reported on 19 patients with vaginal cancer treated with different combinations of EBRT and intracavitary and interstitial HDR brachytherapy, with a low (39.3%), 2-year progression-free survival and 15.8% serious late complications including ureteral stenosis, painful vaginal necrosis, and small bowel obstruction.

Many aspects remain unknown or not well understood in the use of HDR-ICB in vaginal cancer treatment. These include the radiobiological equivalency of HDR to LDR, fractionation schedule, total dose, specification of dose prescription, and how to combine HDR with EBRT and/or LDR brachytherapy. In addition, optimization approaches and methods of dose calculation, such as the inclusion of anisotropic corrections, are not well described in the sparse literature available to date (181,182). Li et al. (182) have shown that when optimized dose distribution at a distance from the cylinder surface is calculated using an accurate dose calculation model, the vaginal mucosa dose becomes significantly higher than calculated, and therefore should be carefully monitored. These factors could result in an increased incidence of severe complications, such as vaginal necrosis and rectovaginal or vesicovaginal fistulas (177,183,184). In our opinion, until further data are available with longer follow-up, as well as a better understanding of the physical and radiobiological principles involved in HDR-ICB, its use should be cautiously considered in the radiotherapeutic management of primary vaginal carcinoma.

Interstitial Brachytherapy

Interstitial brachytherapy (ITB) is an important component in the treatment of more advanced primary vaginal carcinomas, typically in combination with EBRT and/or ICB. In the first place, a careful definition of the “target volume,” which is the gross tumor volume (based on clinical, radiologic, and operative findings) and a margin of adjoining normal tissue, is required. Other considerations include whether a permanent (^{198}Au or ^{125}I) or temporary implant (^{192}Ir) is optimal, the geometry of the implant (e.g., single or double plane or volume implant), source distribution, dose rate, and total dose, based upon tumor size, location, local extent, and proximity of normal structures (185). The principal advantages of temporary

implants are readily controlled distribution of the radioactive sources and easier modification of the dose distribution. The main advantages of a permanent seed implant include relative safety/simplicity, easy applicability, cost-effectiveness, and ability, in most cases, to be performed using local anesthesia. As a general rule, temporary implants are more commonly used in the curative treatment of larger gynecologic malignancies, whereas permanent implants are usually performed for smaller volume disease.

The number and strength of the radioactive sources and their intended distribution within the target volume are determined preoperatively, making use of available guidelines such as nomograms, tables, and computer-assisted optimization techniques. Following this it is necessary to specify an approximate dose rate to the target volume, which requires careful localization of the sources and computer calculation of the 3-dimensional radiation dose distribution. Finally, a dose prescription, based upon the treatment volume, tumor sensitivity, dose rate, prior treatments and tolerance of normal surrounding tissues is required (152).

When performing an interstitial procedure, freehand implants or template systems designed to assist in preplanning and to guide and secure the position of the needles in the target volume can be employed. Popular commercially available templates include the Syed-Neblett device (SNIT) (Alpha Omega Services, Bellflower, California, USA) (186), the modified Syed-Neblett (187), and the “MUPIT” (Martinez Universal Perineal Interstitial Template) (188). All rely on pelvic examination to help guide the location and depth of needle placement. These templates generally consist of a perineal template, vaginal obturator, and 17-Gy hollow guides of various lengths that can be afterloaded with ^{192}Ir sources. The vaginal obturator is centrally drilled so that it can allow the placement of a tandem to be loaded with ^{137}Cs sources. This makes it possible to combine an interstitial and intracavitary application simultaneously (Fig. 20.11). The major advantage of these systems is greater control of the placement of the sources relative to tumor volume and critical structures due to the fixed geometry provided by the template and central cylinder. In addition, improved dose-rate distributions are obtained by means of computer-assisted optimization of the source placement and strength during the planning and loading phase (Fig. 20.12).

Owing to the inaccuracies of pelvic examination and close proximity of the rectum and bladder to the target volume, there exists a serious risk of either underdosing the target volume or causing bladder and rectal morbidity. In order to improve the accuracy of target localization and needle placement, several investigators have explored performing ITB under transrectal

FIGURE 20.11. Syed-Neblett and modified templates.

ultrasound (TRUS) (189), CT and/or MRI-planned implants with endorectal coil (204), laparotomy, and laparoscopic guidance (187–193). While laparotomy facilitates the displacement of bowel during the procedure by using slings or tissue expanders and/or lysis of adherent bowel there is some degree of associated morbidity, such as ileus, bleeding, and increased operative time. Laparoscopy is a shorter and less invasive procedure. An open retropubic approach allows direct visualization of the bladder and urethra during interstitial implantation of anterior vaginal malignancies and facilitates negotiation of the pubic arch. Paley et al. (193) described a technique using an open retropubic approach for Syed template interstitial implants in anterior vaginal tumors under direct visualization. Real time TRUS-guided Syed-Neblett template implantation technique was reported by Stock et al. (189). TRUS allows the ultrasound (US) probe to be in closer proximity to the pelvic structures (cervix, parametria, and vagina) than trans-abdominal US and can more accurately guide needle placement into tumor and avoid needle insertion into critical surrounding normal tissues. Transverse US imaging is used to assure that the needles cover the target area and do not enter the bladder, rectum or small bowel. The longitudinal mode of the US probe is equally important in the implant procedure due to its ability to guide the optimum depth of needle insertion. With this technique, invasive laparotomy and/or laparoscopy can often be avoided, providing an interactive, noninvasive technique allowing for highly accurate needle placement (189).

Shah et al. (194) reported on toxicity after needle puncture of visceral organs during interstitial brachytherapy without assistance of image guidance during the placement (194). They imaged 36 patients after needle placement with a postoperative CT scan and found bowel puncture in 26 patients and bladder puncture in 19 patients; however, they found no relationship between visceral puncture and the incidence of acute or late gastrointestinal or urinary toxicity. They did note that needles that perforated the bowel or bladder were not loaded or the dwell times were minimized in these areas and conclude that toxicity may be related to the dose received by the normal structures rather than the occurrence of visceral puncture (194).

Tewari et al. (195) described results in 71 patients who underwent ITB with (61 patients) or without (10 patients) EBRT. Patients included those with stage I (10 patients), Perez modification stage IIA (14 patients), Perez modification stage IIB (25 patients), stage III (15 patients), and stage IV (7 patients) disease. Each implant delivered a total tumor dose reaching 80 Gy integrated with EBRT. Local control was achieved in 53 patients (75%). With a median follow-up of 66 months the 5- and 10-year actuarial disease-free survival rates were both 58%. By stage, 5-year disease-free survival rates included stage I, 100%; stage IIA, 60%; stage IIB, 61%; stage III, 30%; and stage IV, 0%. Stage and primary lesion size independently influenced the survival rates. Significant complications occurred in 9 patients (13%) including necrosis (n = 4), fistulas (n = 4), and small bowel obstruction (n = 1) (195).

Stryker (196) treated 40 patients with vaginal carcinoma; 14 had a history of prior hysterectomy. There were 4 treatment groups: EBRT and intracavitary brachytherapy (group WPIC, $n = 15$), EBRT and interstitial brachytherapy (group WPIS, $n = 10$), EBRT alone (group WP, $n = 7$), and brachytherapy alone (group BA, $n = 2$). The 5-year disease-specific survival rates were 68% for 28 patients with SCC and 50% for 6 patients with adenocarcinoma. The 5-year survival rates were 78% for stage I disease, 63% for stage II, 33% for stage III, and 50% for stage IV ($p = 0.2$). Local failure occurred in 2 patients (13%) in the WPIC group, 2 (20%) in WPIS, 3 (43%) in WP, and 1 (50%) in BA. Nine patients (26%) had late small/large intestine or bladder morbidity. Vaginal morbidity occurred in 15 patients (44%) (196).

Role of Chemotherapy and Radiation

The control rate in the pelvis for stage III to IV patients is relatively low, and about 70% to 80% of the patients have persistent disease or recurrent disease in the pelvis in spite of high doses of EBRT and brachytherapy. Failure in distant sites does occur in about 25% to 30% of the patients with locally advanced tumors, which is much less than pelvic recurrences. Therefore, there is a need for better approaches to the management of advanced disease such as the use of concomitant chemoradiotherapy. Agents such as 5-FU, mitomycin-C, and cisplatin have shown promise when combined with RT, with complete response rates as high as 60% to 85% (197,198), but long-term results of such therapy have been variable. In these small studies, many of the patients had advanced (stage III) disease at the initiation of combined-modality therapy, perhaps explaining the lack of long-term disease control.

Evans et al. (197) found no local recurrences, however, among patients achieving a complete response with RT and 5-FU plus mitomycin C (12 of 25 patients), with a median follow-up period of 28 months, suggesting that local control may be improved with combined-modality therapy since local failure is common with radiation alone in large-volume pelvic disease. The survival for the entire population was 56% (66% for patients with primary vaginal cancer). Only 2 patients had severe complications, although the investigators recognize that longer follow-up is probably required to assess the true incidence of late effects.

More sobering are the data from Roberts et al. (198), who reported 67 patients with advanced cancers of the vagina, cervix, and vulva treated with concurrent 5-FU, cisplatin, and RT. Although 85% experienced a complete response, 61% of the cancers recurred, with a median time to recurrence of only 6 months and an overall survival at 5 years of 22%. Further, 9 of 67 patients (13%) developed severe late complications, of which 8 required surgeries. Kersh et al. (199) reported that 5 of 8 vaginal cancer patients achieved local control with combined modality therapy.

Dalrymple et al. (200) published a small study including 14 patients, primarily stages I and II SCC of the vagina, treated with reduced doses of RT (median 63 Gy) concurrently with different 5-FU-based chemotherapeutic regimens. They reported a 93% control rate (4 patients died of intercurrent disease with no evidence of tumor), probably reflecting a more favorable stage distribution. Interestingly, none of the patients required interstitial implants and no patients developed fistulas. The authors indicate that this approach, similar to the one used in the management of anal and vulvar cancer, would allow reducing the RT dose with the subsequent improvement in organ function and late toxicity.

Samant et al. (201) reviewed institutional data on 12 patients (50% FIGO St III or IVA) treated with concurrent radiation and weekly cis-platinum chemotherapy (40 mg/m² for 5 weeks). At

a median follow-up of 50 months, the 5-year overall, progression-free, and local relapse-free survival rates were 66%, 75%, and 92% respectively. Sinha et al. (120) reported on 11 of 45 patients that received concurrent cisplatin with radiation that failed to show a benefit in disease control with the addition of chemotherapy; however these patients had more advanced FIGO stages which has shown to be a major determinant of failure and survival.

In a study by Panici et al. (202), 11 patients received neoadjuvant chemotherapy with paclitaxel and cisplatin for 3 courses followed by radical surgery for patients with FIGO stage II vaginal cancer. They found complete clinical responses in 3 (27%) patients, partial clinical responses in 7 (64%) patients, and 1 patient with stable disease (9%). At a median follow-up of 75 months, 91% are alive and 73% are disease-free.

Studies of primary chemoradiation in primary vaginal cancer are small or heterogeneous populations, including cervical and vulvar cancers, making it difficult to truly assess the role of combined-modality therapy in the management of locally advanced disease. No randomized trials comparing radiation with or without chemotherapy have been reported. Further investigation is needed to determine the therapeutic efficacy of the concurrent chemoradiotherapeutic and the optimal chemotherapeutic regimen.

Published data on cervical cancer have demonstrated an advantage in locoregional control, overall survival, and disease-free survival for patients receiving cisplatin-based chemotherapy concurrently with RT (203–206). The only drug common to all the studies was cisplatin, suggesting it may be the only agent needed to improve radiation sensitivity. Based on these data, as well as data on locoregionally advanced vulvar cancer (136,207) consideration should be given to a similar approach in patients with advanced vaginal cancer. In a recent SEER analysis for vaginal cancer, using the year 2000 as a surrogate for the introduction of chemoradiation in cervical cancer, a trend toward lower risk of death after 2000 in their multivariate model was found, as compared with women diagnosed between 1990 and 1994 (HR 0.83, $p = 0.07$) (121). Randomized trials comparing radiation therapy alone to chemoradiation therapy, however, are unlikely due to small patient numbers.

PATTERNS OF FAILURE IN SCC

At least 85% of patients who recur will have a component of locoregional failure, and the vast majority of these recurrences will be confined to the pelvis and vagina. The rate of locoregional recurrence in stage I is approximately 10% to 20% versus 30% to 40% in stage II. The pelvic control rate for patients with stage III and stage IV is relatively low and about 50% to 70% of the patients have recurrences or persistence in spite of well-designed RT. The median time to recurrence is 6 to 12 months. Tumor recurrence is associated with a dismal prognosis, with only a few long-term survivors after salvage therapy (159). Failure in distant sites alone or associated with locoregional failure does occur in about 25% to 40% of patients with locally advanced tumors (Table 20.6) (48,159,208–213). It is important to recognize that analysis of RT doses and techniques and their impact on local/pelvic tumor control are fraught with difficulty since the available data are retrospective and not the result of prospective randomized or dose escalation studies. Andersen (12) has shown that the combination of EBRT and brachytherapy and tumor dose over 70 Gy were associated with improved local control. In the Stanford experience (20), earlier stage and higher RT dose had a positive influence on survival. Nine of 16 patients receiving lesser than or equal to 75 Gy had recurrent disease versus 3 of 22 receiving greater than 75 Gy. Larger series have

Table 20.6 Patterns of Failure: SCC Vagina

Authors	No. of Patients	Percent of Recurrence	Local-regional Recurrence	Distant Recurrence	Local + Distant
Chyle et al. (14)	301	35%	21%	11%	3%
Davis et al. (24)	89	Stage I (23%)	18%	5%	Not shown
		Stage II (36%)	16%	20%	
Kirkbride et al. (16)	153	42%	32%	7%	3%
Kucera and Vavra (123)	110	24.5%	21%	4%	0.5%
Perez et al. (35)	212	Stage 0 (5%)	5%	0	0
		Stage I (22%)	8%	8%	5%
		Stage IIA (47%)	17%	13%	17%
		Stage IIB (71%)	15%	26%	29%
		Stage III (55%)	5%	20%	30%
		Stage IVA (73%)	27%	0	47%
		Total: 42%	13%	12%	17%
Tabata et al. (159)	51	Stage 0–II (36%)	36%	0%	Not shown
		Stage III–IV (92%)	50%	42%	
Urbanski et al. (23)	125	53%	41%	8%	4%
Frank et al. (48)	193	25%	12%	7%	13%

not found a significant impact of the RT dose and recurrence rate, probably because larger tumors received higher EBRT and brachytherapy doses (14,35). The M. D. Anderson series (48) did not find dose lower than or greater than 75 Gy to be associated with improved pelvic control or disease-specific survival, the only 2 statistically significant factors being the stage of the disease and the size of the tumor over 4 cm.

Perez et al. (4,35) observed increased tumor control in patients with stages IIA to IVA with EBRT and brachytherapy compared to patients receiving brachytherapy alone. In patients with stage I disease, no correlation was found between the technique of RT used and the incidence of local or pelvic recurrences. In addition, they suggested that doses in the range of 70 to 75 Gy to the primary tumor volume and 55 and 65 Gy to the medial parametria for patients with more advanced disease are necessary to optimize tumor and pelvic control. Furthermore, of 100 patients with primary tumors involving the upper and middle third of the vagina who received no elective irradiation to the groins, none developed metastatic inguinofemoral lymph nodes, which is in contrast to 3 of 29 (10%) patients with lower-third primaries and 1 of 20 patients with tumors involving the entire length of the vagina. Of 7 patients with initially palpable inguinal lymph nodes treated with doses to around 60 Gy, only 1 developed a nodal recurrence. The investigators recommended that elective RT of the inguinal lymph nodes should be carried out only in patients with primary tumors involving the lower third of the vagina. Similar results were published by Stock et al. (21) and Stryker (196). Lee et al. (150) identified overall treatment time as the most significant treatment factor predicting pelvic tumor control in 65 patients with carcinomas of the vagina treated with definitive RT. If the entire course of RT, including EBRT and brachytherapy, was completed within 9 weeks, pelvic tumor control was 97% in contrast to only 57% when treatment time extended beyond 9 weeks ($p < 0.01$). Conversely, Perez et al. (35) did not find a significant impact of prolongation

of treatment time on pelvic tumor control. Nevertheless, these investigators advocate completion of treatment within 7 weeks to 9 weeks.

TREATMENT COMPLICATIONS AND THEIR MANAGEMENT

Clearly, the knowledge of common acute and late complications with standard RT and consideration of risk factors may improve the therapeutic ratio of RT for gynecological malignancies in general and for vaginal cancer in particular (228). The anatomic location of the vagina places the lower gastrointestinal and genitourinary tracts at greatest risk for complications after surgery or RT. Although in most of the retrospective series, the investigators comment on the nature of the complications encountered, little information is typically given regarding their prevention or management (13,15,21,33,110,133). In modern oncology, survival rate is the primary endpoint in treatment evaluation, but the analysis of treatment complications and quality of life is of crucial importance.

The acute and chronic pathophysiology of vaginal RT has been well described by Grigsby et al. (215). As an immediate response to high-dose RT, there is loss of most or all of the vaginal epithelium, especially in areas in proximity to brachytherapy sources. Clinically, the severity of the acute effects (edema, erythema, moist desquamation, and confluent mucositis with or without ulceration) varies in intensity and duration depending upon patient age, hormonal status, tumor size, stage, RT dose, and personal hygiene. These effects usually resolve within 2 to 3 months after completion of therapy. In some patients, there is progressive vascular damage with subsequent ulcer formation and mucosal necrosis, which may require up to 8 months for healing. Chemotherapy concurrently with RT enhances the

acute mucosal response to both EBRT and brachytherapy. The effects of chemotherapy on the incidence of late complications, if any, are unclear. Over time, most patients will develop some degree of vaginal atrophy, fibrosis, and stenosis. Telangiectasis is commonly seen in the vagina. Vaginal narrowing or shortening, paravaginal fibrosis, loss of elasticity, and reduced lubrication often result in dyspareunia. More severe complications include necrosis with ulceration that can progress to fistula formation (rectovaginal, vesicovaginal, urethrovaginal). MRI may be useful in evaluating complications of the disease and treatment, such as vesicovaginal or rectovaginal fistulas (216).

The RT tolerance limits of the entire vagina are ill defined given the variety of techniques employed for the treatment of vaginal cancers. An irradiation tolerance level of the proximal vagina was suggested by Hintz et al. (217) based on a study of 16 patients who received a maximum surface dose of 140 Gy, without concurrent chemotherapy, none of whom developed severe complications or necrosis of the upper vagina. Based on their previous observation of a patient who developed a vesicovaginal fistula after receiving a 150-Gy mucosal dose to the anterior vaginal wall, they recommended a tolerance dose level of 150 Gy (direct summation of EBRT dose and ICB) to the anterior upper vaginal mucosa. They advocated dose rates of less than 0.8 Gy/hour. These authors cautioned against placing radioactive needles on the surface of the vaginal cylinder because this may increase the frequency of vaginal necrosis. They also recommended keeping the total dose to the distal vagina less than 98 Gy. In addition, it was also observed that the posterior wall of the vagina is more prone to radiation injury than the anterior or lateral walls, and that the dose should be kept below 80 Gy in order to minimize the risk of rectovaginal fistula (217). More conservative doses are recommended when combining RT with concurrent chemotherapy.

Rubin and Casarett (218) suggested that the tolerance of the vaginal mucosa (Tolerance dose 5/5: 5% necrosis within 5 years) is approximately 90 Gy for ulceration and more than 100 Gy for fistula formation. This tolerance limit has been specified as a direct summation of dosage given by LDR-ICB and EBRT in the treatment of cervical cancer. Within the low-dose-rate range, whether a correction for the brachytherapy dose rate is necessary remains controversial. In a series from Washington University, the traditional LDR tolerance dose of 150 Gy to the mucosa of the proximal vagina was shown to yield a nominal 11% and 4% grade 1, 2, and 3 sequelae, respectively (219).

The incidence of grade 2 or higher complications has been reported to be 15% to 25%, (21,23,33,35,48,120,198,220) with the average of severe complications (those requiring surgery for correction or necessitating hospitalization) being approximately 8% to 17% (48,120). Table 20.7 (47,48,208–210,212,213,221,222) shows the incidence of complications greater than grade 2 in several large series of vaginal cancer patients.

In a series by de Crevoisier et al. (118), anterior tumor location was associated with increased bladder toxicity ($p = 0.01$) and decreased rectal toxicity ($p = 0.08$). Vaginal toxicity was associated with the extent of vaginal involvement ($p = 0.02$) and FIGO stage ($p = 0.03$); the total reference air kerma was significantly higher in the group of patients who experienced grade 2 to 3 urinary or intestinal toxicity ($p = 0.03$).

Host factors that may increase the risk of complications include prior pelvic surgery, pelvic inflammatory disease, immunosuppression status, collagen vascular disease, low body weight, patient age, significant smoking history, and comorbid illness (e.g., diabetes, hypertension, and cardiovascular disease) (4,35,48). In Frank et al. (48) series, major complications at 5 years were found in 25% of current smokers compared to 18% in patients who claimed to quit more than 6 months prior to radiation therapy, compared to only 5% in patients who had

Table 20.7 Complications of Therapy (Grade 2)

Authors	No. of Patients	Percent of Complications (Grade 2)
Chyle et al. (14)	310	19% actuarial at 20 years
Kirkbride et al. (16)	153	10%
Kucera and Vavra (123)	110	5.5%
Perez et al. (35)	212	13%
Peters et al. (110)	86	7 (8%)
Rubin et al. (33)	75	15 (23%)
Stock et al. (21)	100	16% actuarial at 10 years
Urbanski et al. (23)	125	13%
Frank et al. (48)	193	5 years, actuarial Stage I, 4% Stage II, 9% Stage III–IVA, 21%

no smoking history ($p < 0.01$). Other factors, such as diabetes and hypertension, were not found to be significant in their series (48).

Perez et al. (4) reported an increase in the rate of severe complications with higher clinical stage, probably reflecting the higher doses delivered with EBRT and brachytherapy. They observed grade 2 to 3 complications in approximately 5% of patients treated for stage 0 and I disease and in approximately 15% of patients with stage II lesions. No complications were reported in stage III and IV disease, probably because few patients lived long enough to manifest complications of treatment. The most common major complications were proctitis (2), rectovesicovaginal fistula (3), and vesicovaginal fistula (2). The most common minor complications were fibrosis of the vagina and small areas of mucosal necrosis, which were noted in approximately 10% of patients.

Lee et al. (150) showed that the total dose to the primary site was the most significant factor predicting the development of a severe complication (9% in patients receiving ≤ 80 Gy as compared with 25% in those receiving higher doses). Perez et al. (19) reported an increase in the rate of severe complications with higher clinical stage, probably reflecting the higher doses delivered with EBRT and brachytherapy.

Ball and Berman (13) reported on 58 patients with carcinoma of the vagina, including 30 who underwent surgery. There were 4 rectovaginal fistulae (1 following RT and 3 after exenterative surgeries) and 2 vesicovaginal fistulae (1 following radical vaginectomy and the other following a recurrence, being managed with cystectomy and diversion). The single ureterovaginal fistula occurred after radical vaginectomy and partial cystectomy and was managed with ureteroneocystostomy.

In the Peters et al. report (110) of 86 vaginal primaries, there were 2 fistulae in the 57 patients who received primary RT. However, there was a 44% rate of fistula formation in the 9 patients who underwent reirradiation after having previously received RT for an earlier cancer. Rubin et al. (33) reported a 23% incidence of complications after RT, including a 13% rate of fistula formation and a 10% rate of cystitis/proctitis. Although 2 patients developed fistulae following combination therapy, the investigators did not think that the rate of complications following combination therapy was greater than that seen following RT alone.

In the Stock et al. series (21) of 100 patients with vaginal carcinoma, there was a 16% actuarial complication rate at 10 years. All patients undergoing vaginectomy or exenteration lost vaginal function. None of the patients was offered vaginal reconstruction in this series. The investigators emphasized that therapeutic options need to be individualized such that surgery is offered only to those most likely to benefit and least likely to suffer complications.

Chyle et al. (14) in 301 patients noted that 39 (13%) had 48 grade 2 or greater sequelae, including rectal ulceration or proctitis in 10 (3 requiring colostomy), small bowel obstruction in 7, rectovaginal fistula in 6, vesicovaginal fistula in 4, vaginoperitoneal/cutaneous fistula in 2, and vaginal ulceration or necrosis in 8 patients. Fewer complications developed in patients with stage 0 or I tumors (8% to 9%) than with more advanced stages (14% to 40%). Vaginal ulceration occurred in 8 of 206 patients (4%) treated with brachytherapy, but in none of 95 patients who received no brachytherapy ($p = 0.06$).

Frank et al. (48) reported 10% and 17% 5- and 10-year cumulative rates of major (greater than grade 2) complications in a series of 193 patients treated with definitive RT with or without chemotherapy. They found FIGO stage and history of smoking to be the 2 factors significantly correlated with subsequent complications. Other clinical, dosimetric factors or the addition of chemotherapy did not correlate with the likelihood of complications. However, 73% of patients with major complications had tumors involving the posterior vaginal wall.

Treatment options for acute radiation vaginitis include daily vaginal douching with a diluted hydrogen peroxide/water mixture (215). This should continue for 2 to 3 months or until the mucosal reactions have subsided. Patients are then advised to continue douching once or twice per week for several months. Regular vaginal dilation is recommended as a way for patients to maintain vaginal health and good sexual function, although the compliance rate is low. The lack of resolution of vaginal ulceration or necrosis after several months of adequate therapy must be appropriately evaluated, considering the possibility of recurrent tumor. The use of topical estrogens following completion of RT appears to stimulate epithelial regeneration more than systemic estrogens. Some patients with severe radiation sequelae, such as fistula formation, will respond to conservative treatment with antibiotics and periodic limited debridement of necrotic tissue. Delanian et al. (223) published a randomized trial demonstrating the effectiveness of the combination of pentoxifyllin and vitamin E in the regression of radiation-induced fibrosis.

Patients with more severe gastrointestinal or urinary late effects will require urinary or fecal diversion with possible delayed reanastomosis. Occasionally, repair of the fistula may be attempted by employing a myocutaneous graft in which the skin, subcutaneous fat, and muscle are mobilized using a vascular pedicle to maintain the blood supply to the pedicled graft (Martius flap), or by excision of the necrotic tissue with reestablishment of organ continuity (such as in the treatment of high rectovaginal fistula). A detailed review of the pathogenesis and management of potential late effects of treatment is not within the scope of this chapter, and may be found in the chapter on management of complications of gynecologic cancer treatment (see Chapter 30).

It is likely that improvements in modern practice such as advancements in surgical techniques (such as more generous use of myocutaneous flaps) (131,224), improved supportive care during the immediate postoperative stay, the use of more sophisticated RT field setting (3-dimensional conformal therapy and IMRT) and treatment delivery, more accurate brachytherapy techniques, and dose calculations have the potential to lessen complication rates post therapy, regardless of which modality is used.

CLEAR CELL CARCINOMA OF THE VAGINA

Since Herbst and Scully's first report (225) of 7 adenocarcinomas arising in the vagina of adolescent females after *in utero* exposure to DES, there have been several reports limited to DES-related vaginal CCA (27–29,41). In 1979, Herbst et al. (306) reported 142 cases of stage I CCA of the vagina. An 8% risk of recurrence was seen after radical surgery ($n = 117$), and an 87% survival was achieved. There was a 36% risk of recurrence after RT for stage I lesions; however, the investigators acknowledged that, in general, RT was reserved for large stage I lesions that involved more of the vault and were less amenable to surgical resection. Surgery for stage I CCA may have the advantage of ovarian preservation and, after skin graft, better vaginal function. As the majority of CCAs occur in the upper third of the vault, the largest series addressing the surgical approach to these lesions have advocated radical hysterectomy, pelvic and para-aortic lymphadenectomy, and sufficient colpectomy to achieve negative margins. Senekjian et al. have also reported a series of exenterations done for CCA (226). However, there have also been efforts to attempt fertility-sparing radical resections (227) or more limited wide local excisions followed by some form of RT (103). Wharton et al. (228) advocate intracavitary or transvaginal irradiation for the treatment of small tumors because this may yield excellent tumor control with a functional vagina and preservation of ovarian function.

Senekjian et al. (103) reported a series of 219 stage I CCA cases of which 176 had conventional therapy and 43 underwent local therapy. The 2 groups appear to be similar with respect to symptoms, stage, location of the lesion in the vagina, greatest tumor diameter, depth of invasion, predominant histologic pattern, grade, and number of mitoses. Actuarial survival rates at 5 and 10 years for the local therapy group (92% and 88%, respectively) were essentially equivalent to those for the conventional therapy group (92% and 90%, respectively). However, the recurrence experience after local therapy was less favorable; at 10 years, the actuarial recurrence rate for the local excision subgroup was 45%, in comparison with only 13% for patients treated with more radical surgery. Local therapy consisted of vaginectomy in 9 cases, local excision alone in 17 cases, and local irradiation (with or without local excision) in 17 cases. The subgroup of patients receiving local irradiation had a recurrence rate of 27%, similar to that of the conventional therapy group and more favorable than that of either the subgroup treated with vaginectomy or local excision alone. Recurrences were more frequently noted in patients with tumors greater than 2 cm, with invasion of ≥ 3 mm, and with a predominant histologic pattern other than tubulocystic. Pelvic lymph node metastases were noted at death in 12% of patients. They advocated a combination of wide local excision and extraperitoneal node dissection followed by brachytherapy for patients desirous of fertility preservation (103).

In a subsequent report, Senekjian et al. (229) reviewed the experience with 76 cases with stage II CCA from the Registry for Research on Hormonal Transplacental Carcinogenesis. The overall 5- and 10-year survival rates were 83% and 65%, respectively. Of the 76 patients, 22 received surgery exclusively (either radical hysterectomy with vaginectomy, 13 patients, or exenterative type procedure, 9 patients), 38 received RT alone, 12 received combination therapy, and 4 underwent other approaches. Patients treated with primary RT achieved an 87% 5-year survival rate versus 80% for those treated with surgery and 85% for those receiving both treatments. The investigators concluded that most patients with stage II vaginal CCA should be treated with combination EBRT and brachytherapy; however, small, easily resectable lesions in the upper fornix might

undergo resection, allowing better preservation of coital and ovarian function (229).

In 1989, Senekjian et al. (226) reported their experience of 20 pelvic exenterations for CCA of the vagina, including 13 for primary lesions and 7 for recurrent disease. The 9 patients with stage II disease treated with primary exenteration were compared with the 67 who had other modalities of therapy; no significant difference in the survival experience was noted between the 2 groups. They reported a 72% success rate if the exenterations were done as part of primary therapy. They advocated reserving exenterative approaches for those who have failed RT in order to maximize quality of life for the greatest number of patients (226).

There are few published reports regarding the use of systemic therapy for CCA. Fowler et al. (230) reported 1 complete and 1 partial response after treatment with melphalan (1 mg/kg qd $\times$ 5 days). Robboy et al. (37) reported responses in recurrent disease to both 5-FU and vinblastine.

NONEPITHELIAL TUMORS OF THE VAGINA

Melanoma of the Vagina

Vaginal melanoma is an exceedingly rare entity. Therefore, the number of patients with vaginal melanoma is too small to permit prospective controlled trials. Melanoma of the vagina, with its propensity to develop distant metastases and its lack of a recognized precursor lesion, has presented therapeutic challenges for surgeons. Investigators have reported small series with generally disappointing results irrespective of treatment modality (245–250). Because of the reputation of melanoma as a radioresistant tumor, it is not surprising that radical surgery has been considered to be the treatment of choice in operable patients. However, limited data are available that validate its efficacy. Although 75% 2-year survival has been achieved after radical excision in small series (236), most series report 5-year survival rates of 5% to 30% regardless of radicality of surgery (38,245–250).

Levitan et al. (235), in their review of the literature, indicated that although the 2-year survival following radical surgery was better (20% to 40%) than with any other therapy, the 5-year survival rates were equally poor (average 8%) regardless of type of therapy. Furthermore, the incidence of distant recurrence was not influenced by the extent of surgical resection. Geisler et al. (233) published the Indiana University experience using pelvic exenteration for malignant melanomas of the vagina or urethra with more than 3 mm of invasion. None of the 4 patients included in this study had recurrences, and 3 patients remained alive with a minimum follow-up of 31 months. Conversely, Bonner et al. (231) reported 9 cases of vaginal melanoma: Three received wide local excisions and 6 underwent radical surgery (including exenterations and radical vaginectomies with or without hysterectomies), with a 29% actuarial 5-year survival rate. All 9 patients suffered locoregional recurrence. The investigators advocated that surgery alone was ineffective in obtaining local control, and that preoperative RT should be considered (231).

Reid et al. (31) reported an overall 17% 5-year survival rate in a report of 15 patients, including 13 who underwent surgery. In addition, they reviewed the literature, summarizing the results achieved in 115 patients with vaginal melanoma, and compared outcomes for the 55 patients who underwent some form of surgery, including the 24 treated conservatively with wide local excision or partial vaginectomy, to the 31 treated with more radical excisions. No difference in survival or disease-free

survival was found among the different surgical procedures (31). In a meta-analysis of essentially the same patient population ($n = 119$ patients), Van Nostrand et al. (236), after adding 8 of their own cases, reached different conclusions. They stated that radical surgery is recommended for patients with primary vaginal melanomas of less than 10 cm². In the Van Nostrand et al. series of their own 8 patients with vaginal melanoma, including 4 treated conservatively and 4 undergoing radical surgery, the only long-term survivor was in the radical surgery group. In their review of the literature, comprising a total of 119 patients, there was 48% 2-year survival rate if treated with radical surgery (50 patients) versus only 20% if treated conservatively (69 patients) ($p < 0.005$). Therefore, Van Nostrand et al. advocated radical excision for those vaginal melanomas less than 10 cm² in area (236).

Not all authors support a radical resection approach. Buchanan et al. (232) performed a literature review of 66 cases reported since the publication of Reid et al. (31). Survival was influenced by tumor size, with a median survival time of 41 months of those with lesions lesser than 3 cm and 21 months in those with larger lesions. However, there was no statistically significant difference in median survival or 2- and 5-year survival among the various surgical strategies. Hence, many investigators have adopted the suggestion of Irvin et al. (234) that if distant failure and death are expected, quality of life should be optimized by wide excision followed by RT to affect local control, while obviating the need for disfiguring radical surgery (182). In the Irvin et al. series (234), all patients treated with wide local excision or brachytherapy alone developed recurrent disease locally, whereas those patients treated with radical surgical resection or with wide local excision followed by high-dose-per-fraction EBRT maintained locoregional control until death.

Recent retrospective data suggest that vaginal melanoma is reasonably radioresponsive and possibly radiocurable (234,237). Volumes and doses of irradiation are similar to those used for epithelial tumors, ranging from 50 Gy for subclinical disease to 75 Gy for gross tumors. Retrospective analysis suggested a dose-response curve of melanoma to external beam irradiation as the dose per fraction is increased and fractions of 3.5 Gy 3 times weekly to 5 Gy twice weekly have been used to treat melanoma because of a large D_{50} observed in *in vitro* studies (238,239). However, the Radiation Therapy Oncology Group conducted a prospective randomized study (RTOG 83–05) (240) evaluating the effectiveness of high-dose-per-fraction irradiation in the treatment of melanoma. Patients with measurable lesions were randomized to 4 $\times$ 8.0 Gy in 21 days once weekly to 20 $\times$ 2.5 Gy in 26 to 28 days, 5 days a week. One hundred thirty-seven patients were randomized and 126 patients were evaluable; stratification was performed on lesions lesser than 5 cm or $\geq$ 5 cm. There was no difference between the 2 arms in terms of response rate (complete responses 24.2% and 23.4% in the 4 $\times$ 8.0 Gy and in the 20 $\times$ 2.5 Gy arms, respectively) (240).

Harwood and Cummings (241) described a complete response in 4 patients with vaginal melanoma treated with irradiation, although 2 subsequently relapsed; complete response to irradiation was seen in 1 patient who was alive and well 10 months after treatment. Harrison et al. (242) reported that 1 of 3 patients with vaginal melanoma treated with irradiation survived 7.5 years; the other 2 died with distant metastases but had local tumor control. Rogo et al. (243) reported on 22 cases of vulvovaginal melanoma treated with conservation surgery or irradiation, or both. Eight patients (36%) were alive 5 years after treatment, and 4 were alive 10 years after treatment. Inguinal lymph node recurrences and distant metastases were the most common modes of failure. Results were comparable with those obtained with radical surgery.

In the Petru et al. series (237) of 14 patients, the 3 long-term survivors received either primary RT after biopsy only,

or adjuvantly after local excision. Tumor size was found to be prognostically important, with 43% of patients with tumors ≤ 3 cm surviving longer than 5 years, compared with 0% of patients with tumors greater than 3 cm. The median overall survival was 10 months, and the 5-year DFS and overall survival rates were 14% and 21%, respectively. The authors concluded that prolonged local control could be obtained with RT as an adjunct to more limited surgery, or even with RT alone, primarily in patients with lesions ≤ 3 cm in diameter.

In summary, given that the high incidence of distant metastasis remains a major factor in limiting curability, a more conservative treatment approach might be more reasonable in selected patients. Patients with vaginal melanoma should probably be managed in a manner similar to that recommended for cutaneous lesions (244). Wide local excision with 1- to 2-cm margins should be the surgical treatment of choice for most primary vaginal melanomas since radical surgery has failed to improve long-term survival. The role of adjuvant RT is unclear, but it appears to improve survival in some series. The use of systemic chemotherapy and/or immunotherapy has been very disappointing in the limited published data (245).

Sarcomas of the Vagina

Sarcomas represent 3% of vaginal primaries (5), with leiomyosarcoma representing 50% to 65% of vaginal sarcomas. Unfortunately, most of the sarcomas are diagnosed at an advanced stage. Histopathologic grade appears to be the most important predictor of outcome. Most vaginal leiomyosarcomas arise from the posterior wall of the vagina. Radical surgical resection, such as posterior pelvic exenteration, offers the best chance for cure for vaginal leiomyosarcomas (5,246). The largest series on vaginal sarcomas reported to date included 17 cases, of which 35% had received prior RT. This series, which included ten leiomyosarcomas, 4 malignant mixed müllerian tumors (MMMTs), and 3 other sarcoma types, noted that all were resistant to chemotherapy, and all of the failures were first noted as pelvic recurrences. There were only 3 survivors seen, and all had undergone exenterative surgery. The 5-year survival rate was 36% in patients with leiomyosarcoma and 17% in those with MMMT (247).

Vaginal MMMTs occur more commonly in postmenopausal women. In approximately half of the cases there is a history of prior pelvic RT (247,248). Despite surgery and adjuvant RT, patients usually do poorly, with a high incidence of local and distant recurrences. The treatment of choice is complete surgical resection, followed by EBRT and ICB in an attempt to decrease the local recurrence rate.

The roles of adjuvant chemotherapy and RT in vaginal sarcomas have not been clearly defined, primarily owing to limited patient numbers and even fewer data where chemotherapy was used as the primary treatment rather than as salvage therapy at recurrence. Adjuvant RT seems to be indicated in patients with high-grade tumors and locally recurrent low-grade sarcomas. According to Peters et al. (247), the most common site of failure is the pelvis. In 50% of patients with recurrence, it is the only site of failure. Extrapolating data from the Gynecologic Oncology Group (249) for uterine sarcomas and considering patterns of failure, patients with localized MMMTs would be appropriately treated with pelvic exenteration, or with more limited surgical resection followed by postoperative RT, unless the patient has received prior pelvic RT. Since patterns of failure suggest that local therapies only reduce the local recurrence rate and do not improve survival, consideration should be given to adjuvant treatments with agents that are active in similar tumors arising in the uterus. Agents found to be active in MMMT of the uterus include ifosfamide, cisplatin, and paclitaxel, although it remains unclear whether any combination of these agents is better than

ifosfamide alone, which has produced the highest response rate among these agents (250,251). Doxorubicin remains the standard therapy for leiomyosarcoma (252).

Embryonal rhabdomyosarcoma (RMS) of the vagina, the most common pediatric vaginal tumor, is such a rare lesion that no single institution has sufficient experience to identify superior therapeutic strategies. Rather, cooperative efforts through the Intergroup Rhabdomyosarcoma Study Group (IRSG) through numerous clinical trials have demonstrated that the use of multimodality therapy with wide local excision and cytotoxic chemotherapy with or without RT makes it possible to avoid exenterative surgery and optimize quality of life for these young patients (251–255). Prior to the modern era of multimodality therapy, Hilgers reported that only 20% to 30% 5-year survival rates were achieved with the use of exenterative-type surgery alone (256). Later, several small series noted that 70% survival could be achieved if RT and combination cytotoxic chemotherapy including vincristine, actinomycin D, and cyclophosphamide (VAC) were given in addition to radical surgery (256–258). After complete resection, irradiation of the entire pelvis is not required, thus avoiding its adverse effects.

In a series of reports from the IRSG, survival rates in excess of 85% have been achieved utilizing VAC chemotherapy and wide excision with or without adjuvant RT, sparing the great majority of patients from exenterative surgery (253–255,259,260). In a subsequent report, Andrassy et al. (261) from the IRSG summarized the outcome of 72 patients with embryonal RMS of the vagina treated on 4 IRSG trials. Over the course of the 4 IRSG trials, the need for radical resection decreased from 100% to 13%, with continued improvement in disease-free survival (261). Andrassy et al. suggested that after biopsy to document RMS, multiagent induction chemotherapy with doxorubicin, cisplatin, vincristine, actinomycin D, and cyclophosphamide should be utilized, then local resection undertaken, with radical resection being reserved for those with persistent or recurrent disease (261). In addition, several non-IRSG series have shown that combination chemotherapy with or without RT leads to sufficient tumor shrinkage, and that less radical resections can become feasible (259,260), allowing preservation of anatomy and function.

Flamant et al. (259) reported 11 cases of vaginal RMS (8 stage I, 2 stage II, 1 stage III) in whom 100% survival was achieved with multimodality therapy. Eight patients received neoadjuvant chemotherapy, generally a VAC regimen, and all patients underwent brachytherapy (doses of 26 to 75 Gy), followed by maintenance chemotherapy and VAC alternating with VAD (vincristine, doxorubicin, dacarbazine). Seven patients underwent ovarian transposition in an attempt to preserve function. The investigators noted partial ovarian insufficiency in 1 patient without ovarian transposition. They recommended brachytherapy at a total dose of approximately 50 to 60 Gy (259).

Lymphomas and the Vagina

Lymphomatous involvement of the vagina most often represents metastatic spread from another primary site. Although surgery (including radical hysterectomy, pelvic lymphadenectomy, vaginectomy, and exenteration) has been performed in the past, more recent reports suggest that combination RT and chemotherapy can achieve excellent results. Radical surgery in such patients then should be avoided, as lymphoma represents a systemic disease. Following biopsy, patients with lymphoma should be managed with chemotherapy alone or combined chemoradiation. Extrapolation from patients with similar tumors arising in extranodal sites would suggest that RT has its primary role in preventing local recurrence in patients who present with bulky disease. In some patients who have a rapid and complete response to multiagent chemotherapy, RT may not be indicated

since the combination of both modalities increases the risk of second malignancies. Harris and Scully noted in a clinicopathologic series of 25 lower genital tract lymphomas, including 4 vaginal lymphomas, that definitive local therapy prevented relapse (262). Prevot et al. (263) and Perren et al. (264) also advocated the use of less extensive surgery, with RT plus cytotoxic multiagent chemotherapy such as CHOP (cyclophosphamide, hydroxydaunomycin [doxorubicin], Oncovin [vincristine], prednisone) or BACOP (bleomycin, Adriamycin [doxorubicin], cyclophosphamide, Oncovin [vincristine], prednisone) for 4 to 6 cycles to affect local control with better preservation of fertility in patients with stage IE and nonbulky tumors of low and intermediate grade.

Yolk Sac (Endodermal Sinus) Tumors of the Vagina

Prior to the use of multiagent cytotoxic chemotherapy, less than 25% of patients with yolk sac tumor (YST), or endodermal sinus tumor (EST), of the vagina survived. However, Young and Scully noted 100% survival in a small series of 6 patients who had received chemotherapy (265). The VAC regimen in conjunction with surgery or RT was advocated by Copeland et al. (257). Collins et al. (266) reported on the use of combination bleomycin, vinblastine, and platinum (BVP) for patients with EST of the vagina. Aartsen et al. (267) reported a successful pregnancy following surgery and chemotherapy. Most recently, Hwang et al. have reported 2 cases, one of which did well with partial vaginectomy followed by 2 years of VAC; however, the second patient developed a central persistence following wide local excision and VAC, but was salvaged with bleomycin, etoposide, and platinum (BEP) (268). Given the excellent results that 3 to 4 cycles of BEP have achieved in malignant germ cell neoplasms of the ovary (269), it is likely that BEP will become the preferred regimen for EST of the vagina used in conjunction with partial vaginectomy, as it requires less prolonged administration and is less oophorotoxic than VAC. It appears that routine use of combination chemotherapy in the management of endodermal sinus tumor allows conservative surgery with preservation of sexual function in young patients, with excellent prospects for long-term survival.

The role of radiation in this disease is limited because of the younger age at presentation, and preservation of ovarian function is desired; in addition, RT would potentially increase the risk for secondary malignancies (270,271), which may be even more significant with the use of IMRT as the volume of irradiation receiving lower doses is generally larger (272). Brachytherapy may occasionally be used, and in one instance, preservation of hormonal function and subsequent pregnancy were reported (267).

OTHER UNCOMMON VAGINAL CANCERS

SCC of the Neovagina

In situ and invasive carcinomas arising in the neovagina are rare, and this type of malignancy seems to be related to the transplanted tissue. A few cases of SCC have been described after split-thickness skin graft vaginoplasty in patients with vaginal agenesis (273–275), as well as after radical vulvovaginal resection for known malignancy (276). Mucinous adenocarcinoma has been described arising in the sigmoid colon used for the reconstruction of the neovagina (277). Neovaginal malignant melanoma following surgery and radiation therapy for vulvovaginal malignancies, although extremely rare, has been reported (278),

suggesting the potential role of radiation-induced melanoma in non-sun-exposed areas such as the genital tract.

Malignant transformation occurs in the neovaginal epithelium, in relation with local carcinogenic environmental factors as well as possible viral infection, with the subsequent risk of malignancy. Therefore, it is important to emphasize the need for regular follow-up visits with Pap smears. The elapsed time between the construction of the neovagina and the development of malignancy ranges between 10 and 30 years. The optimal treatment is not well defined. Radical surgery resection when possible should be the treatment of choice, since definitive RT seems to be associated with higher failure rates (227). Adjuvant RT could be considered in patients with positive margins or positive nodes (277).

Carcinoma in Episiotomy Scar

Episiotomy scar tumor implantation from a cervical or vulvar carcinoma is a very rare event. Van Dam et al. (279) reported on 3 cases of primary or metastatic carcinoma in an episiotomy scar. One patient had a primary SCC of the vulva in an episiotomy scar; a second patient was diagnosed with cervical carcinoma 6 months postpartum and was found to have a metastatic deposit in the episiotomy scar during the staging of her disease; the third patient developed adenocarcinoma metastatic from an endocervical primary in an episiotomy scar that presented as a small nodule at the introitus. These cases exemplify the need for careful inspection and biopsy of any nodular lesions in episiotomy scars as part of the initial assessment and follow-up of patients with premalignant or malignant lesions of the lower genital tract. Early initial stage, small size lesion, and early therapy appear to improve prognosis. Treatment needs to be individualized given the rarity of this entity. Patients with limited recurrent disease at the episiotomy site without any other evidence of locoregional recurrence could be treated with surgical resection followed by tailored radiation therapy. Patients with more advanced disease may be offered radiation with or without chemotherapy followed by surgical resection when feasible (280,281).

SALVAGE THERAPY

In general, the patient with recurrent cancer of the lower female genital tract presents a difficult clinical dilemma. Optimal therapy for patients with recurrent gynecologic cancer after potentially curative therapy has not been completely defined, partly owing to the difficulty of conducting prospective, randomized trials in this heterogeneous population. It must be determined if the disease is amenable to curative salvage therapy, implying some reasonable chance of cure, or whether palliation is the primary goal. Treatment selection factors include primary therapy, extent of the disease at presentation, site of recurrence, extent of the recurrence, disease-free interval, evidence of metastatic disease, patient age, performance status, and coexisting medical conditions.

The presence of distant metastasis portends a poor prognosis, and although chemotherapy may result in objective responses and improvements in short-term survival, the current lack of curative systemic treatments focuses therapeutic attempts on symptom palliation and quality of life. In most cases, only patients with small volume local recurrences and no metastatic disease are curable. Therefore, careful workup to establish extent of disease is crucial. When salvage therapies are contemplated, local recurrences should be confirmed by biopsy, and, when possible, parametrial recurrences should be documented pathologically. Pelvic sidewall involvement can almost always be diagnosed in the presence of a symptom triad of sciatic pain,

leg edema, and hydronephrosis. It is important to evaluate for regional and/or distant metastasis by physical examination and imaging studies such as CT or MRI scans. More recently, the positron emission tomography (PET) scan has been used to document the extent of recurrent disease (282), but both false-positive and false-negative results have been reported.

Generally, patients with isolated pelvic or regional recurrences after definitive surgery who have not received prior RT are managed with EBRT, often in conjunction with brachytherapy (16,21,24). Concurrent cisplatin-based chemotherapy may also be recommended (23). Salvage options for patients with central recurrence after definitive or adjuvant RT are limited to radical surgery, usually exenterative (16,21,23,24). In selected patients with small volume disease, reirradiation using interstitial radiation implants or highly conformal 3-dimensional EBRT may be feasible. Response rates with chemotherapy are low and the impact on survival is limited. Further, response to chemotherapy in central pelvic recurrences following RT tends to be less common than response at distant sites. Additionally, prior high-dose radiation therapy compromises bone marrow tolerance of many agents that are active in this tumor (e.g., ifosfamide and doxorubicin). However, chemotherapy-responsive patients can obtain meaningful palliation in many cases.

Surgical Considerations

Despite thorough clinical evaluation of patients considered being excellent candidates for salvage surgery, this will be aborted in over 25% of the cases because of advanced disease found at the time of the exploratory laparotomy (283). Pelvic exenteration results in long-term functional and psychological changes that have not been adequately studied (284). Surgical refinements have done much to improve body image changes associated with pelvic exenteration. The purposes of vaginal and perineal reconstruction following radical pelvic surgery for recurrent gynecologic cancer are primarily twofold: to restore or create vulvovaginal function, and thereby minimize the effects of surgical treatment on body image and normal sexual activity, and to minimize postoperative complications by transferring to the pelvic defect healthy tissue with a good blood supply (155,156). A detailed review of urinary diversion and pelvic reconstruction techniques is not within the scope of this chapter.

Radiation Therapy Considerations

Those patients who have not received prior RT should receive whole-pelvis EBRT followed, when feasible, by brachytherapy. Generally, the whole pelvis receives a dose of 40 to 50 Gy. Inguinofemoral lymph node regions should be included in patients with involvement of the distal third of the vagina or with vulvar recurrences. The gross tumor volume in the vagina, paravaginal tissues, and/or parametrium should receive an additional boost, preferably with an interstitial implant, to bring the total tumor dose to 75 to 80 Gy. The role of combined chemoradiotherapy in the management of patients with recurrent disease is unknown. Given the rarity of vaginal carcinoma and the heterogeneity within the population with recurrent disease, large randomized studies intended to answer this question will probably never be conducted. However, by extrapolation from the available data for locally advanced cervical and vulvar cancer (136,203–207), it seems that a combined modality approach may improve the locoregional control and survival in patients with isolated pelvic recurrences.

Reirradiation in previously irradiated patients must be undertaken with extreme caution. However, selected patients who are medically inoperable, technically unresectable, or refuse to undergo exenterative surgery are appropriately considered for reirradiation to limited volumes. A variety of techniques is available,

and the choice is based on patient and tumor-related factors, as well as the experience of the radiation oncologist. When using EBRT, multiple-beam arrangements utilizing 3-dimensional treatment planning are favored. Only limited doses are possible, and the physician might consider a hyperfractionated regimen in an attempt to decrease the incidence of late toxicity.

In patients with small, well-defined vulvovaginal or pelvic recurrences, reirradiation using primarily interstitial techniques has been attempted with control rates between 50% and 75% and grade 3 or higher complication rates between 7% and 15% (285–389). The rationale, logistics, and selection of implant technique when performing an ITI were reviewed earlier in the chapter. Permanent radioactive seed implants (e.g., ¹⁹⁸Gold) in patients with small vaginal recurrences often provide long-lasting tumor control in elderly or medically debilitated patients previously treated with definitive doses of RT (301). In a series by Brabham and Cardenes (307), 19 patients with low volume recurrent gynecologic malignancies (4 vaginal primaries) were treated with permanent interstitial implants using ¹⁹⁸Gold. Complete response was observed in almost 95% of patients and local control was achieved in 63%; however the authors emphasize that these results are in a selected patient population with small volume recurrences no thicker than 1 cm (161).

Other potential treatment options include the use of surgery and intraoperative RT (IORT) with intraoperative electron beam (290,291), laparotomy, or laparoscopically guided placement of HDR catheters (192,291–293), which allows direct visualization of the target volume and displacement and/or shielding of the surrounding normal tissues. However, the published series are generally small, including a wide spectrum of patients with different gynecologic malignancies, varying amounts of residual disease, and disparate initial therapies. The locoregional recurrence and distant metastasis rates after IORT vary between 20% and 60% and 20% and 58%, respectively. The 3- to 5-year actuarial survival is poor, ranging from 8% to 25%. Grade 3 or higher toxicity has been reported in about 35% of patients (290,291). In the Memorial Sloan-Kettering Cancer Center experience using radical surgical resection and HDR-IORT, patients with complete gross resection had a 3-year local control rate of 83% compared to 25% in patients with gross residual disease. Interestingly, most of the failures in the microscopic group were distant, perhaps indicating a potential role for adjuvant chemotherapy (292).

Hockel et al. (293) described a combined operative and radiotherapeutic treatment (CORT) for the treatment of recurrent gynecologic malignancies infiltrating the pelvic side wall. The procedure involves gross complete resection of the tumor and a single plane interstitial implant. In order to improve the therapeutic index, well-vascularized tissue is transposed to the pelvis to protect the hollow organs and reduce the late effects of RT. Reconstruction of pelvic organs is performed as with exenteration. The tumor bed is irradiated postoperatively, days 10 to 14, using HDR brachytherapy. In a total of 48 patients treated with this technique, the overall severe complication rate was 33% at 5 years. The 5-year survival rate was 44%, and the absolute local control rate was 60% for the first 20 patients and 85% for the last 28 treated patients (293).

Stereotactic body radiotherapy (SBRT), also known as extracranial stereotactic radioablation (ESR), is a novel treatment paradigm that delivers a small number of high-dose fractions to extracranial targets using a linear accelerator with highly precise, accurate, and reproducible target localization based on the same principle as that of gamma-knife therapy. By means of better target localization and patient immobilization, smaller margins of normal tissue surrounding the gross tumor volume are required, which allows treatment complications to be minimized. Blomgren et al. (294) reported on 15 patients with 19 extrahepatic abdominal tumors who had a mean survival of 17.7 months. The toxicity was more often self-limited except for

4 patients with gastrointestinal bleeding. They concluded that this treatment, which is noninvasive, painless, rapid, and does not require hospitalization, does not impair the quality of life of the patients when used properly. Additional 3 reports in the literature describe using SBRT for primary or recurrent gynecological malignancies (220,295,296).

Molla et al. (296) used SBRT in place of a brachytherapy boost in 16 patients (14 primary and 2 patients with recurrent disease). SBRT doses of 2 fractions of 7 Gy or 4 fractions of 5 Gy were used and the authors report high rates of local control with only 1 local failure. One patient in their series had late rectal complications with grade 3 rectal bleeding 18 months after reirradiation for a vaginal vault relapse.

Guckenberger et al. (295) reported on 19 patients that were treated with stereotactic body radiotherapy for a local boost in unfavorable locally recurrent gynecological cancers (12 recurrent cervical cancers and 7 recurrent endometrial). The majority of patients were treated with conventionally fractionated EBRT followed by a stereotactic boost because the large volume and/or peripheral location of the recurrence made vaginal brachytherapy inappropriate as a sole boost technique. Three patients received SBRT only. The mean dose delivered with EBRT was 50 Gy and the mean stereotactic dose was 3 fractions of 5 Gy prescribed to the 65% isodose line. The local control rate for these recurrences was 81% after 2 and 3 years. The rate of late toxicity greater than grade 2 was 25%, with 2 patients suffering from intestinovaginal fistula and 1 patient from small bowel ileus.

PALLIATIVE THERAPY

Radiation Therapy

At the present time, there is no curative option for patients who present with stage IVB disease. Many of these patients suffer from severe pelvic pain or bleeding. If vaginal bleeding is the main concern, ICB, if feasible, often offers good symptom control with relatively low morbidity. For patients who have

received prior RT, intracavitary doses in the range of 35 to 40 Gy to point A should be prescribed.

A short course of EBRT using high-dose fractionation schedules has been used, including single doses of 10 Gy per fraction, times 3, with an interval of 4 to 6 weeks between courses, combined with misonidazole (RTOG clinical trial 79-05), resulting in significant palliation in selected patients with advanced gynecologic malignancies. The overall response rate was 41% for patients completing the 3 courses; however, the actuarial 45% incidence of grades 3 and 4 late gastrointestinal toxicity was unacceptable (297).

Spanos et al. (298) reported on a Phase II study (RTOG 85-02) of daily multifraction split-course EBRT in patients with recurrent or metastatic disease. The regimen consisted of 3.7 Gy per fraction given twice daily for 2 consecutive days and repeated at 3- to 6-week intervals for a total of 3 courses (tumor dose 44.4 Gy). Occasionally, this regimen was combined with an intracavitary implant (ICI) (4,500 mgh), with a midline block in the last 14.4 Gy. Complete tumor response was noted in 15 patients (10.5%) and partial response in 32 (22.5%). In patients completing 3 courses of irradiation (59%), the rate of complete or partial response was 45%. Twenty-seven patients survived longer than 1 year. Late complications were significantly fewer, with a projected actuarial rate of 5% at 12 months. In a subsequent Phase III study (299), 136 patients were randomized between rest intervals of 2 versus 4 weeks between the split courses of RT. Decreasing the interval between courses did not result in a significant improvement in tumor response (34% vs. 26%). More patients in the 2-week rest group completed the 3 courses of therapy, and not surprisingly, patients completing all 3 courses had a higher overall response rate than patients completing less than 3 courses (42% vs. 5%) and a higher complete response rate (17% vs. 1%). This schedule offers significant logistic benefits, and has been shown to result in good tumor regression and excellent palliation of symptoms (299). Spanos et al. (300) reported a trend toward increased acute toxicity in patients with shorter rest periods, but late toxicity was not significantly different in the 2 groups (Fig. 20.13).

FIGURE 20.13. Palliative course of external beam irradiation using the RTOG 85-02 regimen. CT scan prior to initiation of therapy (A); AP (B) and lateral DRRs (C) of the initial fields; CT scan after 2 split courses of hypofractionated irradiation (2950 cGy) in 1 week (D). AP (E) and lateral DRRs (F) of the cone down fields prior to a brachytherapy boost; AP (G) and lateral radiographs (H) of the brachytherapy implant.

FIGURE 20.13. Continued

Chemotherapy in Advanced and Recurrent Vaginal Cancer

Given its rarity, most chemotherapy reports for treatment of metastatic disease in vaginal cancer are anecdotal or combined with reports of treatment of advanced or recurrent cervical cancer. Concurrent chemoradiation is frequently employed in clinical practice in the treatment of unresectable, locoregionally advanced disease. Various chemotherapeutic agents have been

used with limited success (197,198). Evans et al. (197) reported on 7 patients with vaginal cancers who were treated with a combination of 5-FU 1,000 mg/m²/day for 4 days, mitomycin C 10 mg/m² day 1, and primary irradiation, receiving 2,000 to 6,500 cGy. All of the vaginal cancer patients responded, and 66% were alive with a median follow-up of 28 months. Treatment of recurrent or metastatic disease is confined to a handful of phase 2 clinical trials and anecdotal reports. In general, regimens that are active in cervical cancer are usually active

FIGURE 20.13. Continued

in vaginal cancer. Thigpen et al. (251) reported the results of a Phase II trial of cisplatin 50 mg/m² every 3 weeks in 26 patients with advanced or recurrent vaginal cancer. There were 22 evaluable patients, 16 with SCC, 2 adenosquamous carcinoma, 1 CCC, 1 leiomyosarcoma, and 2 unspecified. Of the 16 SCC patients, there was 1 complete response (6.2%). It should be noted that these patients, for the most part, had received prior surgery and RT. Muss et al. (301) reported no responses in 19 evaluable patients who were treated with mitoxantrone 12 mg/m² every 3 weeks. Median survival of patients with vaginal cancer was 2.7 months. Other anecdotal reports of responses in trials that included advanced cervical cancer include a report by Long et al. (302) in which 3 patients with advanced vaginal SCC received treatment with methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC). All 3 patients achieved a complete response of short duration. Patton et al. (303) reported the results of intra-arterial chemotherapy with mitomycin C, bleomycin, cisplatin, and vincristine, including 6 patients with primary vaginal cancer and 40 patients with cervical cancer. Seventy-six percent responded to intra-arterial chemotherapy and subsequently received primary RT. The report did not give details as to site of relapse, impact on disease-free survival, or overall survival.

At the present time, data on systemic treatment of advanced vaginal cancer outside of a clinical trial is purely anecdotal, although it might be reasonable to extrapolate from the experience reported with SCC of the cervix and vulva (136,203–207). Although published response rates are low, standard therapy should include cisplatin alone or in conjunction with RT in patients with locoregionally advanced vaginal cancer.

SUMMARY AND CONCLUSIONS

The malignant histologies of the vagina are so rare that randomized clinical trials have not been undertaken. It is difficult to establish strong, evidence-based recommendations in such a rare disease as cancer of the vagina. Therefore, future progress will

likely come from reports from single institutions. Most of the available data refer to the treatment of primary invasive SCC of the vagina, since this represents the most common histology. The following management recommendations are made based on the available data.

Vaginal Intraepithelial Neoplasia

In patients with unifocal disease, partial colpectomy has come to be favored over laser vaporization, since there is an approximately 25% risk that there can be underlying invasive disease, and one-quarter to one-third of patients will require a second laser vaporization to effect long-term control. However, for patients who develop VAIN following radiation wherein colpectomy would be associated with a higher risk of fistulae development, there may be a role for laser vaporization and/or topical 5-FU application. Intracavitary brachytherapy alone has provided satisfactory functional and local control results as well.

Invasive SCC

Although RT can control many cases of vaginal cancer, local control remains a problem. The treatment of invasive SCC with RT should include the use of brachytherapy, with particular attention to technique that ensures that the treatment volume is adequately covered. In larger tumors, the dose that is needed to achieve local control may well exceed the tolerance of surrounding normal tissues. Although not specifically proven for patients with vaginal primaries, the addition of chemotherapy (i.e., weekly cisplatin) as a radiosensitizing agent may help to improve these results if the strong evidence in locally advanced cervical cancer can be extrapolated to vaginal cancer. Although there are multiple series that demonstrate excellent results with radical surgery for well-selected early-stage patients, RT will continue to be the primary modality even for early-stage disease and for those elderly patients with multiple comorbid conditions.

Clear Cell Adenocarcinoma

It has been suggested that patients with early-stage disease may be offered fertility-sparing combined modality local therapy with extraperitoneal node dissection and wide local excision followed by brachytherapy with acceptable local failure rates. However, advanced-stage disease would require primary RT. Patients who have completed childbearing would be best served by radical hysterectomy, colectomy, and lymphadenectomy. Exenteration should be reserved for those patients who have isolated central failures following definitive RT.

Melanoma

The risk of distant metastases is high enough that most modern investigators have suggested that ultra-radical surgery, although it might improve 2-year survival rates, has not led to an increase

in long-term survival. Wide excision followed by RT to affect local control may obviate the need of disfiguring surgery in those likely destined to develop distant metastases.

Sarcoma

The trials conducted by the IRSG and others have demonstrated that pediatric embryonal RMS of the vagina is best approached with induction multiagent-combination therapy, such as VAC, followed by local resection with or without brachytherapy, with radical surgery being reserved for those with persistent or recurrent disease. Patients with adult-onset vaginal sarcoma do not respond as well to chemotherapy, and the only long-term survivors are those who have been offered exenterative surgery.

EPIDEMIOLOGY, ETIOLOGY, AND RISK FACTORS

Worldwide, cervical cancer is the third most common malignancy and the second most common cancer (after breast cancer) in women. Nearly one-half million new cases occur each year. In 2012, it is estimated that 12,170 women will be diagnosed with invasive cervical cancer in the United States and over a third of them (4,220) will likely succumb to the disease (1). These statistics stand in sharp contrast to those of the developing nations where cervical cancer is the second leading cause of cancer death in women with well over 500,000 new cases annually worldwide and over 250,000 deaths. These are thought to be underestimations of the true numbers and burden of the disease. These disparate statistics and toll are due to paucity of screening programs and lack of access to life-saving treatments for women diagnosed with preinvasive and invasive cervical cancer. The disease burden in the United States is disproportionate among minority and economically burdened populations (1). Over 50% of cervical cancers diagnosed in the United States occur in women with no prior screening and around 10% are in women without any screening in the preceding 5 years.

The incidence and mortality of this disease in North America have declined during the last half century owing to both increased availability of Pap smear screening and a decrease in fertility rate. An extensive discussion of cervical cancer etiology and risk factors appears earlier in the text, particularly in Chapters 1 to 3 and 8. The reader is referred to those chapters for detailed information.

ANATOMY

The uterus, situated in the center of the pelvis, is composed of a muscular layer (myometrium) and mucosal glandular layer (endometrium), which lines a hollow cavity extending from the top of the uterus (fundus) through the lower uterine segment connecting to the endocervical canal. The endometrial cavity is surrounded by the myometrium. The three segments of the uterus include the fundus, body, and isthmus (lower uterine segment). Anteriorly, the lower uterine segment is attached to the bladder peritoneum (vesico-uterine pouch), which requires dissection and separation to expose the cervix. This compartment between the bladder and uterus is the anterior cul-de-sac. Posteriorly the peritoneum lines and separates the lower uterine segment and cervix from the rectum, creating the posterior cul-de-sac (pouch of Douglas). The cervix is an extension of the lower uterine segment and can be divided into vaginal and supravaginal components. The cervix varies in length, averaging 3 to 5 cm.

Centrally located in the vaginal portion is the external cervical os, which connects to the endocervical canal, the internal cervical os, and the endometrial cavity.

The cervix is a fibrous organ lined by squamous and columnar cells. The transition from columnar cells to squamous cells occurs in the region of the cervical os in what is termed the transformation zone. Most dysplastic and malignant cervical lesions arise from this area. The endocervix contains mostly mucinous glandular epithelium with similar morphology to that of the fallopian tube.

The uterus has 5 ligamentous attachments. Specifically these include the round, broad, utero-ovarian, cardinal, and utero-sacral ligaments. The round ligaments run from both sides of the fundus anterolaterally on top of the broad ligaments to the pelvic sidewall, where they are closely related to the inferior epigastric vessels and continue on their path to leave the pelvis through the inguinal ring and canal. They contain a vessel known as Sampson's artery as well as other small vessels and nerves.

The broad ligaments attach to the lateral margin of the uterus on either side and extend underneath the round ligaments from above the cervico-uterine junction and to the pelvic sidewall. These ligaments are covered by peritoneum anteriorly and posteriorly, and are relatively thinner above the cervico-uterine junction. Within the leaves of the broad ligament are extraperitoneal connective tissues known as the parametrium, which surround the lower uterine segment and the cervix.

The utero-ovarian ligaments originate just below the fallopian tubes and directly connect to the ovaries. The cardinal ligaments, also known as Mackenrodt's ligaments, are thickened extensions of the broad ligaments attaching laterally from the lower uterine segment (isthmus) and the cervix. They course to the lateral vaginal wall and rectal pillars and extend to the pelvic sidewalls.

Each cardinal ligament helps create and define 2 important anatomical spaces, the pararectal and paravesical spaces, which are important in the surgical treatment of early cervical cancer. The cardinal ligament covers a portion of the pelvic ureter, which lies underneath the uterine artery and above the uterine vein about 2 cm away from the isthmus. It contains uterine, vaginal, middle rectal, and inferior vesical arteries and veins as well as lymphatic tissue and channels.

Two important anatomical landmarks during radical hysterectomy (RH) for treatment of early cervical cancer are the paravesical and pararectal spaces. The paravesical space is lateral to the bladder and can be opened by dissection underneath the insertion of the round ligament into the pelvic sidewall. This space is opened using blunt dissection underneath the round ligament dissection along the curve of the bony pelvic wall proceeding medially to open the relatively avascular space. The anterior wall is bounded by the superior pubic ramus, the medial wall is the bladder and vagina, the lateral wall is composed of the external iliac vessels and parts of the obturator fossa, and

the posterior wall is formed by the cardinal ligament, separating this space from the pararectal space. This space can be continuous with the space between the bladder and the pubic bone, known as the space of Retzius. The pararectal space is found between the ureter laterally and the origin of the hypogastric artery medially and follows the curve of the sacrum. Anteriorly it is bounded by the cardinal ligament. The lateral wall is formed by the hypogastric vessels. Medially it is bounded by the ureter, and the floor is composed of the curve of the sacrum down to the levator muscles. During a RH, these two spaces allow for direct examination of the parametrium to determine extent of the disease and the resectability of the primary tumor allowing for free surgical margins.

The utero-sacral ligaments connect laterally to the cervix and lower uterine segment medial to the ureters. They run from the posteriolateral segment of the cervix over the top of the antero-lateral portion of the rectum and attach to the rectal wall and the sacrum. The cardinal and utero-sacral ligaments provide the bulk of support for the uterus and cervix.

The blood supply of the uterus is mainly through the uterine artery, originating from the anterior division of the hypogastric artery. An important landmark during a RH, the uterine artery spawns cervical and vaginal branches that supply the cervix, and then extends superiorly to the fundus where its tributaries supply the fundus and the body of the uterus. The uterine artery also descends toward the vagina and gives off a vaginal branch. The ovarian vessels originating from the aorta also contribute to the blood supply of the uterus. There is a rich anastomosis between the uterine and ovarian arteries. Other potential collateral blood supply to the uterus may be from the branches of the posterior division of the hypogastric, the ilio-lumbar artery, or other vessels supplying the pelvis such as middle sacral artery, and pudendal and obturator arteries. The venous drainage follows the arterial supply.

The lymphatic drainage of the cervix is rich and complex. Laterally from the cervix, the lymphatics drain into the paracervical and parametrial lymph nodes and to the internal, external, and common iliac chains. The obturator lymph nodes are the most medial portion of the external iliac nodal region and play a key role as one of the first sites of lymphatic spread of cervical cancer following the parametrial nodal tissues. Other lymphatic drainage routes include the inferior and superior gluteal lymph nodes and the superior rectal, presacral, and paraaortic lymph nodes. The innervations of the cervix are from the sacral roots (S2–4) crossing through the hypogastric plexuses.

NATURAL HISTORY

Preinvasive Disease

Cervical cancer is preceded by an interval of epithelial dysplastic changes, typically in the transformation zone, known as cervical intraepithelial neoplasia (CIN), which may progress to invasive cancer. Low-grade dysplasia (CIN 1) is confined to the basal one-third of the epithelium, whereas high-grade dysplasia (CIN 2 to 3) involves two-thirds or greater of the epithelial thickness. Full thickness involvement is known as carcinoma *in situ* (CIS), which is thought to be the most significant precursor lesion for invasive squamous carcinoma. Cytologic screening has helped in decreasing the incidence of cervical cancer in the United States and other developed nations dramatically. Of approximately 55 million Pap smears performed in the United States annually, 5% to 7% are abnormal, and the majority of these are atypical squamous cells of undetermined significance (ASCUS) (2). The majority of the disease burden is in developing nations where screening and treatment programs are scarce and difficult to implement.

Many studies have evaluated the natural history of cervical dysplasia. Holowaty et al. evaluated cervical dysplasia in about

17,000 women with mild, moderate, and severe dysplasia (3). The reported risk of progression from mild to severe dysplasia was 2% and 6% at years 2 and 5, respectively. However, progression from moderate to severe dysplasia was 16% and 25% at 2 and 5 years, respectively. The relative risks of progression from severe dysplasia to CIS and invasive cancer were 4.2 and 2.5, respectively, 2 years after diagnosis of dysplasia. The majority of mild dysplasias (CIN 1) regressed to normal within 2 years.

In a meta-analysis of 15 studies of 27,929 women, Melnikow et al. found 2-year progression rates to high-grade dysplasia to be 7% and 21% from ASCUS and low-grade dysplasia, respectively (4). The rate of progression to invasive cancer for ASCUS was 0.25%, as compared to low-grade dysplasia (0.15%) and high-grade dysplasia (1.4%). The regression rates to normal for ASCUS, low-grade, and high-grade dysplasias were 68%, 47%, and 35%, respectively.

The incidence of progression from CIS to invasive cancer in patients with persistent abnormal cytology after initial treatment was 24.8 times greater than in those who had normal cytology after initial treatment (5). Overall the reported rate of progression of CIS to invasive cancer ranges from 12% to 22%.

Most low-grade dysplasia will regress to normal in about 24 months. Therefore, only careful follow-up is warranted. However, women with high-grade disease or CIS should be more closely evaluated and treated aggressively as the risk of progression is higher (5). A great deal is being learned about the natural history of this disease; as there are many variations including a subset of CIS lesions that can rapidly present as invasive cancer within a couple of years. Many glandular lesions associated with HPV 18 can also herald a rapid progression to invasive disease proving evasive even in adequately screened populations. Emerging data strongly suggest that despite negative cytology, a woman who tests positive for highly oncogenic HPV 16 has a significantly higher chance of having or developing CIS. These will be discussed in detail in the screening section.

Patterns of Spread

Cervical cancer can spread through direct extension to the endocervix, lower uterine segment, parametrium, vagina, and, less often, to the bladder and/or rectum. It can also spread lymphatically to the parametrial, obturator, and internal, external, and common iliac lymph nodes. Inferior and superior gluteal, superior rectal, presacral, and paraaortic lymph nodes can also become involved. The pattern of spread is usually predictable and orderly, as the rate of paraaortic lymph node metastasis is very rare if the pelvic nodes are spared. The overall risk of pelvic lymph node metastasis in stage IB is about 9% to 17% (6,7). The risk of paraaortic nodal (PANL) metastasis is higher with advanced stage disease, with rates of 16% and 25% for stage II and III, respectively (8). Scalene nodal involvement is reported to be between 10% and 23%, and involvement of higher paraaortic nodes can suggest possible scalene nodal involvement (9).

The most common sites of hematogenous spread include lung, mediastinum, bone, and liver. Other less common sites are spleen, brain, and adrenal gland. Most recurrences occur in the first 24 months, with a median of 17 months.

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

Preclinical Invasive Disease

Screening and Cytology

The effectiveness of screening cytology is related to the ease of obtaining specimens, the sensitivity of the test, and a long

dysplastic phase that can be detected via cytology and effectively treated with high success rates. There are currently 2 primary means of obtaining and diagnosing cervical dysplasia. One is the conventional Pap smear and the other is liquid-based thin layer preparation.

Using classification as low-grade squamous intraepithelial lesion (LSIL) as the threshold, Nanda et al. reported a large variation in the sensitivity of conventional smears, with published data ranging from 30% to 87%; specificity was much higher at 86% to almost 100% (10). Cytologic screening is a continuum in which specificity is increased through sequential testing. The most common reasons for false-negative smears are errors in sampling and preparation. In 1996, liquid-based cytology was introduced in the United States. Cells are obtained by a cytobrush and transferred into a buffered alcohol medium. The suspended cells are then plated in a thin, evenly distributed layer, improving the clarity of the slide for evaluation. Another benefit is that the specimen can be tested for HPV, gonorrhea, and chlamydia. A careful review of data suggests that liquid-based cytology may be superior to conventional cytology in minimizing the number of unsatisfactory smears and increasing detection rates of low- and high-grade abnormalities (11). Sulik et al. reported no difference between the 2 methods in a large systematic review (12). The American Cancer Society (ACS) and U.S. Preventive Services Task Force (USPSTF) have concluded that, although liquid-based technology may be more sensitive than conventional cytology, there was insufficient evidence to recommend universal adoption. The American College of Obstetricians and Gynecologists (ACOG) does not support changing screening intervals based on the method of screening (13).

The changes in recommendations for screening published in 2012 have been sweeping. Screening is not recommended in anyone under the age of 21 regardless of the age of sexual debut. For women aged between 21 and 29, cytology alone is recommended every 3 years. HPV testing is not recommended in this age group, as there is a high prevalence of infection in this population, with many being transient. The rationale is that cotesting with HPV will only increase the number of colposcopies and will result in harm without reducing the risk of CIN 3 or invasive cancer. For patients aged 30 to 65, the recommendations are for cytology alone every 3 years versus cytology and HPV co-testing every 5 years, with the latter being the preferred recommendation.

Screening should stop at age 65 for women with 3 negative consecutive previous cytology results or 2 consecutive negative cytology and HPV testings within the last 10 years, with the most recent being within last 5 years. Once screening is discontinued, it should not be resumed even if the woman has a new sexual partner (14,15). It is important to note that following regression or appropriate clinical treatment of CIN 2 or 3 and AIS, screening should continue for 20 years, even if that exceeds the threshold of 65 years of age. Annual screening results in an over 50% increase in the number of colposcopies when compared to screening every 3 years, without adversely affecting the outcomes.

Women who have undergone hysterectomy for a prior diagnosis of CIN 2 or 3 or a more severe diagnosis should continue screening for 20 years. Those with no prior history of cervical dysplasia should not undergo routine vaginal cytology. Women who have been vaccinated for HPV should follow the age-specific recommendations, since 30% of cervical cancers are caused by etiologies other than HPV 16 and 18.

If HPV is negative and cytology is ASCUS, then rescreening with co-testing in 5 years or with cytology alone in 3 years is reasonable. If HPV is positive and cytology is negative, then a 12-month follow-up with repeat co-testing or subtesting for HPV16 and 18 can be done and, if positive, should herald a referral for colposcopy given the high rate of coexistent CIN 2 or 3 with positive testing for types 16 or 18. If the subtyping is negative, then a 12-month follow-up with co-testing is reasonable.

Detection of adenocarcinoma is much more difficult than detection of squamous lesions. HPV 18 positivity with negative cytology may indicate a significant underlying glandular lesion (16).

To provide a standard terminology for reporting cytologic findings, the Bethesda system set forth guidelines in 1988, with revisions in 2001 (17). This system describes the adequacy of the specimen, a general categorization of whether it falls within normal limits or not, and a description of the dysplastic cytologic abnormalities detected in 3 categories: ASCUS or atypical squamous cells—cannot rule out high-grade squamous intraepithelial lesion (ASC-H), LSIL (the same as CIN 1), and high-grade squamous intraepithelial lesion (HSIL), which is the same as CIN 2 or 3. It can also report squamous cell carcinoma directly. For glandular lesions, categories include atypical glandular cells (AGS), denoting origin if possible (endocervix, endometrial, or not otherwise specified), AGS favoring neoplastic, adenocarcinoma *in situ* (AIS), or frank adenocarcinoma.

It is estimated that approximately 10% to 20% of women with ASCUS or ASC-H have underlying CIN 2 or 3 and that 1 in 1,000 may have underlying invasive cancer. ASC-H is expected to be diagnosed in about 5% to 10% of all ASCUS readings. AGS is associated with a much higher percentage of high-grade disease when compared to ASCUS—as high as 39%.

The ASCUS/LSIL Triage Study (ALTS), a multicenter randomized trial of 3,488 women, compared immediate colposcopy versus triage to colposcopy based on HPV testing, and liquid-based cytology with a threshold of HSIL versus conservative management with triage based on repeat cytology with a threshold of HSIL (18,19). ASCUS was reproducible in repeat liquid-based cytology in only 32% of cases with an overall CIN 2 and 3 diagnosis of 15% when ASCUS cytology was further investigated. HPV testing was able to identify 92% of women who would ultimately have a diagnosis of CIN 3. Only 1.4% of women with negative HPV testing developed CIN 3 over 2 years. If HPV testing was positive with LSIL or ASCUS was the same around 27%. Repeat cytology for ASCUS would have referred almost 67% of women to colposcopy as compared to HPV testing, which referred about half the number of women for colposcopy. The American Society of Colposcopy and Cervical Pathology (ASCCP) endorsed HPV testing as the preferred method of triage for ASCUS smears detected by liquid-based cytology (20).

HPV Testing

HPV DNA testing is a new tool that has gained greater popularity and utility in the last few years. It is especially useful in women over 30 when combined with cytology, because it provides much greater sensitivity for detection of CIN 2–3 disease, although it is less specific (16). Methods of detecting HPV include hybrid capture 2 and polymerase chain reaction. Both tests have similar sensitivity and specificity, but the former is easier to perform technically, especially in a large screening program setting. Sherman et al. studied over 20,000 women, evaluating the role of conventional Pap smear and concurrent HPV testing to determine the risk of developing CIN 3 (21). In this study, 72% of women who developed CIN 3 had baseline abnormal cytology and positive HPV testing with a cumulative incidence of developing CIN 3 or invasive cancer of 4.5% in approximately 45 months of follow-up. This was compared with women with negative smears and HPV testing whose cumulative incidence of developing CIN 3 or invasive cancer was only 0.16%. The combination of negative cytology and HPV testing carries a high-negative predictive value of over 95% for the development of CIN 3 or invasive cancer, providing great reassurance for low-risk women and lengthening the interval of screening in that population.

Clavel et al. studied the role of HPV testing as a primary screening tool in almost 8,000 women (22). They reported 100% sensitivity of HPV testing in detecting histologically proven

high-grade dysplasia compared to conventional smear (68%) and liquid-based cytology (87%). The specificity of HPV testing was 93% in women over 30, compared to conventional and liquid-based technologies with specificities of 86% and 95%, respectively. Overall it was found that HPV testing is much more sensitive in detecting high-grade disease compared to conventional smears, but with a lower specificity rate. This approach requires further study; screening women younger than 30 years may lead to unnecessary testing, as many HPV infections are transient, and most women will not develop dysplasia with HPV infection. In LSIL, more than 85% of cases test positive for HPV. Therefore, HPV testing is not encouraged. CIN 2 and 3 require immediate referral for colposcopic evaluation. The overall 2-year cumulative risk of developing CIN 2 and 3 for LSIL and ASCUS with positive HPV testing was essentially the same (27.6% and 26.7%). The authors suggested that repeat HPV testing 12 months after diagnosis of LSIL and ASCUS with positive HPV yielded the highest sensitivity and lowest rate of referral for colposcopy. Repeat cytology with HPV testing did not significantly increase sensitivity and increased referral for colposcopy. HPV testing appears to be useful in triage of ASCUS smears, possibly reducing colposcopic referrals by almost 50% (17,18). HPV subtyping for 16 and 18 may even be more helpful in further delineating the risk of CIN 3 and subsequent risk of invasive cancer. HPV 16 is found in 55% to 60% of all cervical cancers. A patient with a positive test for HPV 16 has a high risk of CIN 3 or more severe lesion of almost 30% if there is persistent HPV 16 infection for around 2 years. CIN 3 has a roughly 30% chance of progression to invasive cervical cancer over a three-decade period, and treated CIN 3 has less than a 1% risk. CIN 3 is the greatest predictor of development of cervical cancer (16).

A large study (ATHENA) that included 40,901 evaluable patients with positive HPV testing and liquid-based cytology test results was recently reported. Of these, 4,275 women (10%) tested HPV-positive and 2,617 (6%) had abnormal cytology. Four hundred and thirty-one women were diagnosed with CIN 2 or worse, and 274 with CIN 3 or worse. In the subset of women who had colposcopy, the HPV testing was more sensitive than liquid-based cytology for detection of CIN 3 or worse (92% vs. 53.3%). The addition of liquid-based cytology to HPV testing improved sensitivity for CIN 3 or worse to 96.7%; however, this contributed to a greater number of positive screenings (by 35%) compared with HPV testing alone. The rate of positive testing for HRHPV was 6.7%, and 1.5% were positive for types 16 and 18. Overall incidence of CIN 2–3 was 1.2%. The absolute risk of a CIN 2 or worse lesion was 11.4% if positive for HPV 16/18 compared to 6.1% if positive for HRHPV and 0.8% if HPV-negative. These results highlight the importance of types 16 and 18 in the development of CIN 3 and a referral for colposcopy if positive, despite negative cytology (23).

Two commercial tests for HPV DNA have been approved by the U.S. Food and Drug Administration. The hybrid capture II test has been shown to have excellent interlaboratory reliability and reproducibility (24).

Colposcopy

Colposcopy examines the lower genital tract including the vulva, vagina, and epithelium of the cervix and opening of the endocervix. The use of acetic acid and Lugol's solution assists in highlighting abnormal and dysplastic changes. Changes such as aceto-white plaques and vascular abnormalities such as punctations, mosaicism, and abnormal branching may signify high-grade disease. Indications for colposcopy include an abnormal-appearing cervix, persistent postcoital bleeding or discharge, persistent CIN 1, 2, or 3 on cytology, *in utero* exposure to DES, and ASCUS smears with positive high-risk HPV testing (16 and 18). In order to have an adequate colposcopic examination the entire transformation zone must be fully visualized.

Endocervical curettage (ECC) can be helpful if positive; however, its role as a routine procedure is debated. Positive predictive value of colposcopy can be increased by multiquadrant biopsies.

Conization Biopsy

Cervical conization refers to the surgical removal of the squamocolumnar junction. This may be done in the operating suite through a classical cold knife conization technique or as an outpatient procedure using thermal cautery with loop excision. Indications for conization include inadequate colposcopy, positive ECC, persistent CIN 1 (usually >1 year), CIN 2, CIN 3, or CIS, and discrepancy between cytologic, colposcopic, or pathologic findings.

Loop Electrosurgical Excision Procedure

Loop diathermy, an alternative to cold knife conization, is usually performed on an outpatient basis. Trials have demonstrated loop electrosurgical excision procedure (LEEP) to be as effective as cold knife conization, with advantages in terms of cost, anesthesia, and ease of use (25). A disadvantage is that significant thermal artifact can hamper evaluation of margin status, which can be minimized with careful technique avoiding prolonged contact with the tissue.

Clinical Disease

Symptoms and Complaints

The most common presentations of invasive cervical cancer are abnormal vaginal bleeding, postcoital bleeding, and vaginal discharge. However, many women are asymptomatic and are found to have disease upon pelvic examination or cytologic evaluation. As the tumor enlarges, it can cause local symptoms such as pelvic pain and difficulty with urination or defecation. As the disease metastasizes to regional lymph nodes, back pain, leg swelling (especially unilateral), and neuropathic pain may occur.

Physical Findings

The most common finding on physical examination is an abnormal lesion on the cervix, at times necrotic and friable. Possible extension onto the vaginal wall should be assessed. Determination of parametrial, sidewall, and uterosacral ligament involvement must be done through a rectovaginal examination. Other areas of concern are the superficial groin and femoral lymph nodes and the supraclavicular region.

Diagnostic Biopsy

Suspicious lesions on the cervix and surrounding areas should be biopsied with enough depth to assure adequate nonnecrotic tissue to render diagnosis. Biopsy on the margin tends to yield better results.

Staging

Clinical Staging Procedures

The most critical component of staging is a thorough pelvic examination, including a rectovaginal exam. If necessary, an exam under anesthesia allows for a careful visual and digital examination as well as cystoscopy and proctoscopy.

Laboratory Studies

A complete peripheral blood count is indicated to evaluate for anemia, which might warrant correction. Thrombocytosis is

found in up to 30% of patients with locally advanced disease, and has been associated with larger tumor size, parametrial involvement, and poorer survival. Serum chemistries with attention to serum creatinine are essential to evaluate for renal failure or to assess renal function in patients who will receive cisplatin-based chemoradiotherapy. Additional tests should include liver function and urinalysis.

Serum Tumor Markers

Though several tumor markers are thought to be useful as prognostic and predictive markers in response to treatment, risk of relapse, and overall survival (OS) in women with cervical cancer, their role in the initial diagnostic evaluation is limited (26,27). Elevation of the most commonly studied tumor markers, squamous cell carcinoma antigen (SCCA), cytokeratin fragment 19 (CYFRA 21.1), and cancer antigen 125 (CA-125), has been observed in 20% to 88% of women with newly diagnosed cervical cancer (26). These elevated levels have been correlated with tumor stage, tumor size, cervical stromal invasion, lymphovascular space invasion, parametrial involvement, and lymph node status (26). In a retrospective study by Huang et al. (28), pre- and posttreatment levels of SCCA and carcinoembryonic antigen (CEA) were evaluated in 188 women with squamous cell carcinoma (SCC) of the cervix receiving concurrent chemoradiation. Pretreatment marker levels predicting high risk for para-aortic lymph node recurrence (66.5% at 5 years) were SCCA ≥ 40 ng/mL or the combination of CEA ≥ 10 ng/mL and SCCA < 10 ng/mL, for intermediate risk were SCCA 10 to 40 ng/mL, and for low risk were both SCCA and CEA < 10 ng/mL (28). Kotowicz et al. (29) assessed pelvic and paraaortic lymph nodes in 182 untreated patients with cervical cancer (87% SCC and 13% adenocarcinoma) and evaluated levels of the tumor markers SCCA, CYFRA 21.1, CA-125, and CEA, and the cytokines interleukin-6 (IL-6) and vascular endothelial growth factor (VEGF). SCCA, CA-125, and IL-6 were significantly higher in women with lymph node metastases than in those with no lymph node involvement. The simultaneous elevation of SCCA and CA-125 levels or SCCA and IL-6 was statistically significant in women with lymph node metastases.

Sheng et al. (30) evaluated SCCA, CYFRA 21.1, CEA, and a nuclear protein found to play a role in tumor development, growth, and metastases, high mobility group box-1 (HMGB1), in early detection of recurrent SCC of the cervix. In 112 women with recurrent SCC of the cervix, 174 women without evidence of recurrent cervical cancer, and 128 age-matched healthy controls, HMGB1 levels were significantly higher in women with recurrent cervical cancer than in women from the other groups ($p = 0.027$). Measurements with the combined tumor markers HMGB1, SCCA, and CYFRA 21.1 were reported to increase the diagnostic sensitivity and specificity (30). Further studies are required to confirm the use of tumor markers alone or in combination for the early detection of recurrence.

Radiographic Studies

In accordance with the International Federation of Gynecology and Obstetrics (FIGO) system for staging, clinical evaluation is the predominant tool for staging cervical cancer (31–33). Non-invasive radiographic imaging studies such as chest radiography, intravenous pyelography (IVP), cystoscopy, sigmoidoscopy, and barium enema may aid in this process but are not mandatory (31–33). Additionally, radiographic studies such as computed tomography (CT), positron emission tomography (PET), combined PET/CT, and magnetic resonance imaging (MRI) are not considered integral to formal staging, but may aid in determination of extent of disease in the pelvis and lymph nodes, evaluation of prognosis, measurement of response, and assessment of recurrence following initial treatment (34–37).

Given that evaluation of the extent of disease in the pelvis and lymph nodes is important for individualizing treatment, advanced imaging with CT, PET/CT, and MRI should be performed preoperatively when available (37). MRI and CT imaging are the most valuable imaging techniques for evaluation of disease in the pelvis and chest/abdomen, respectively. Due to its superb soft tissue delineation, high-resolution MRI with contrast and diffusion-weighted imaging is useful for the evaluation of disease in the pelvis assessing tumor size, extension into the uterine corpus, depth of stromal invasion, parametrial and pelvic wall extension (34,35). In a randomized, prospective study performed by the American College of Radiology Imaging Network (ACRIN) and the Gynecologic Oncology Group (GOG), MRI more accurately determined tumor diameter, uterine extension, and parametrial involvement than did CT or clinical examination in early invasive cervical cancer (38–41). However, in large, bulky cervical tumors, MRI may overestimate parametrial extension and may less accurately determine upper vagina, bladder, and/or rectum invasion (34).

PET/CT plays a valuable role in the imaging of nodal metastases (36,42–44). Kidd et al. reported a large prospective study to evaluate the role of pretreatment [^{18}F] fluorodeoxyglucose PET imaging for lymph node staging in 560 women with clinical stage IA1–IVB disease (42). The frequency and pattern of lymph node metastases on PET were associated with clinical staging. Although this study did not confirm lymph node status by histopathology, disease-specific survival correlated with PET-positive lymph nodes. Choi et al. published a meta-analysis comparing the diagnostic performance of CT, MRI and PET or PET/CT for detection of nodal metastases in 41 published reports (43). PET or PET/CT showed the highest pooled sensitivity (82%) and specificity (95%), while CT showed 50% and 92%; and MRI, 56% and 91%, respectively (43). Kang et al. performed another meta-analysis assessing the diagnostic value of PET for the evaluation of PALN metastases in 10 published reports (44). Their analyses indicated assessment of PALN metastases by PET or PET/CT is acceptable for higher stage cervical cancer, but for earlier stage disease, PALN dissection is preferable. In summary, PET or PET/CT has a higher diagnostic performance for detecting lymph node metastases than CT or MRI, especially in women with higher-stage cervical cancer.

Future studies combining MRI and PET may provide additional staging information. In a retrospective study by Kim et al., lymph node status was evaluated comparing MRI/PET fusion and PET/CT prior to lymphadenectomy in 79 women with histologically confirmed invasive Stage IB–IVA cervical cancer (45). Review of lymph node status with MRI/PET fused images revealed identification of 6 additional metastatic nodal groups in 3 additional patients as compared to PET/CT images. Sensitivity and specificity of PET/CT was 44.1% and 93.9%, respectively, while for fused MRI/PET was 54.2% and 92.7%, respectively (45).

In conclusion, both MRI and PET/CT imaging modalities are recognized as being very useful in the staging and subsequent treatment planning of this disease. There is further interest in performing dynamic contrast-enhanced MRI to evaluate tumor vascularity and perfusion, and PET/CT to evaluate intratumoral metabolic activity, and using this information to predict response to therapy (46–48). As the technology of these imaging modalities continues to advance, integration of both anatomic and biologic information will permit further individualization of treatment.

FIGO and American Joint Committee on Cancer Staging

The staging system used for cervical cancer is based on the FIGO staging system, updated in 2009 (33). The main change from the 1995 staging system involves stage IIA. Stage IA is microscopic, with IA1 defined as stromal invasion to less than 3 mm in depth and no more than 7 mm wide, and stage IA2 defined as stromal invasion 3 to 5 mm deep with width no greater than 7 mm. The Society

of Gynecologic Oncology (SGO) also considers negative lymphovascular space invasion (LVSI) and margin status as criteria for microinvasive disease (MID). The horizontal spread must be 7 mm or less to be considered MID according to FIGO, but SGO does not include lateral spread in defining MID. The diagnosis of MID must be made on a conization or hysterectomy specimen. Punch biopsies are not adequate. Stage IB involves the cervix only. It is divided into IB1, which includes all lesions greater than IA2 and no more than 4 cm in greatest dimension, and stage IB2 for lesions measuring greater than 4 cm. Stage II invades beyond the uterus but not to the pelvic wall or to the lower third of the vagina. It is divided into A and B. Stage IIA involves the proximal vagina and is now subdivided similarly to stage IB into IIA1, which includes tumors less than 4 cm, and IIA2 for tumors greater than 4 cm involving the proximal vagina and sparing the parametrium. Stage IIB indicates parametrial invasion. In Stage III, the tumor extends to the pelvic wall and/or involves

lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney. Stage IIIA extends to the lower third of the vagina sparing the pelvic sidewall, while IIIB extends to the pelvic wall and/or causes hydronephrosis or nonfunctioning kidney without alternate reason for such findings.

Surgical findings and radiographically guided biopsies of suspected lesions such as lymph nodes or lung metastasis cannot be used to change or modify clinical FIGO staging. In Stage IV, the tumor extends beyond the true pelvis or has involved the mucosa of the bladder or rectum (biopsy proven). Bullous edema alone does not permit a case to be allotted to stage IVA. Stage IVB denotes distant metastasis. A tumor-node-metastasis (TNM) staging system proposed by the American Joint Committee on Cancer (AJCC) corresponds well to the FIGO clinical staging. The current criteria for the various stages are defined in Table 21.1. TNM is mainly used in documenting findings on surgical and pathologic evaluations as the pathologic stage of the disease,

Table 21.1 Definition of TNM

TNM Categories		FIGO Stages
<i>Primary Tumor (T)</i>		
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
Tis	0	Carcinoma <i>in situ</i>
T1	I	Cervical carcinoma confined to uterus (extension to corpus should be disregarded)
T1a ^a	IA	Invasive carcinoma diagnosed only by microscopy. Stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium and a horizontal spread of 7.0 mm or less. Vascular space involvement, venous or lymphatic, does not affect classification
T1a1	IA1	Measured stromal invasion ≤3.0 mm in depth and ≤7.0 mm in horizontal spread
T1a2	IA2	Measured stromal invasion >3.0 mm and ≤5.0 mm with a horizontal spread ≤7.0 mm
T1b	IB	Clinically visible lesion confined to the cervix or microscopic lesion >T1a/IA2
T1b1	IB1	Clinically visible lesion ≤4.0 cm in greatest dimension
T1b2	IB2	Clinically visible lesion >4.0 cm in greatest dimension
T2	II	Cervical carcinoma invades beyond uterus but not to pelvic wall or to lower third of vagina
T2a	IIA	Tumor without parametrial invasion
T2a1	IIA1	Clinically visible lesion ≤4.0 cm in greatest dimension
T2a2	IIA2	Clinically visible lesion >4.0 cm in greatest dimension
T2b	IIB	Tumor with parametrial invasion
T3	III	Tumor extends to pelvic wall and/or involves lower third of vagina, and/or causes hydronephrosis or nonfunctioning kidney
T3a	IIIA	Tumor involves lower third of vagina, no extension to pelvic wall
T3b	IIIB	Tumor extends to pelvic wall and/or causes hydronephrosis or nonfunctioning kidney
T4	IVA	Tumor invades mucosa of bladder or rectum, and/or extends beyond true pelvis (bullous edema is not sufficient to classify a tumor as T4)
<i>Regional Lymph Nodes (N)</i>		
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N1	IIIB	Regional lymph node metastasis
<i>Distant Metastasis (M)</i>		
M0		No distant metastasis
M1	IVB	Distant metastasis (including peritoneal spread, involvement of supraclavicular, mediastinal, or paraaortic lymph nodes, lung, liver, or bone)

Note: The definitions of the T categories correspond to the stages accepted by the Fédération Internationale de Gynécologie et d'Obstétrique (FIGO). Both systems are included for comparison.

^aAll macroscopically visible lesions—even with superficial invasion—are T1b/IB.

and FIGO is used for clinical staging. All histologic types are included. If there is ambiguity regarding the correct stage, the lower stage is assigned.

Pretreatment Nodal Staging

The presence of paraaortic lymph node metastases has a significantly negative impact on progression-free and overall survival. Pretreatment knowledge of paraaortic spread could potentially direct treatment in a manner that could improve outcomes. Given the limitations of imaging in reliably detecting paraaortic micro-metastases, surgical staging has been used. However, the role of surgical staging for locally advanced cervical cancer remains unclear. The use of PET/CT scans has become widely adopted in Western countries with a relatively low sensitivity rate of 30% to 40%, depending on the study. However, a relatively high negative predictive value of 80% to 90% has been reported in various studies. Ramirez et al. studied 65 patients with stages IB2 to IVA comparing radiographic (PET/CT) versus surgical staging of paraaortic nodes (49). Positive PA nodes were found in 23%; 22% of those with positive histologic nodes had negative radiographic findings. PET/CT was superior to CT or MRI alone when nodes were negative on those modalities, with a specificity of 96%. Treatment was modified in 18% due to surgical findings. Kidd et al. evaluated 560 patients with PET/CT and correlated finding with prognosis (50). Almost half (47%) had positive nodes on PET/CT, which conferred a poor prognosis with a hazard ratio of recurrence based on positive nodes, depending on location of pelvic, paraaortic, and supraclavicular, of 2.4, 5.8 and 30, respectively. Gold et al. reviewed 555 patients with surgical paraaortic node sampling and 130 who had radiographic staging. For stages III and IV, the 4-year progression-free survival (PFS) was 49% versus 36%, with an OS of 54% versus 40%, favoring patients who were surgically staged (51).

With the advent of laparoscopy and the presumed lower morbidity, there has been some renewed interest in surgical nodal assessment as a method to refine treatment. Faggotti et al. reviewed 13 published series to investigate the role of pretreatment laparoscopic staging. They showed laparoscopic surgical staging can be performed safely and contribute to tailor treatment. However, the positive impact on DFS has still to be demonstrated (52).

Leblanc et al. evaluated 184 patients with stages IB2 through IVA with pretreatment extraperitoneal laparoscopic staging of paraaortic nodes (53). They found a 24% incidence of PANL involvement and an operative complication rate of 2%. They had a 13% symptomatic lymphocyst rate that decreased to about 3% with modification of techniques. Findings of surgical staging changed the management of 20% of patients who would have received only pelvic radical trachelectomy (RT) to extended field RT. Data suggested a survival advantage in patients with resected positive nodes.

Lai et al. compared clinical staging versus surgical staging (laparoscopic or extraperitoneal approach) in 61 patients (54). PANL metastasis was detected in 25% of the surgical group. The study was terminated early, as the surgical arm had a significantly worse progression-free and overall survival compared to the nonsurgical arm. The question of pretreatment surgical staging remains controversial, and ongoing prospective studies are in progress to determine the utility of surgical staging in the setting of quality PET/CT imaging (49–51).

Sentinel Lymphatic Mapping in Early Cervical Cancer

The standard surgical treatment for early cervical cancer (stages IA2 to IIA) is RH and pelvic lymphadenectomy (PL). The PL is complete and removes all nodal bearing tissues on the external iliac artery and vein (up to the circumflex iliac vein), internal iliac artery above the obturator nerve, and common iliac artery

up to the iliac bifurcation. The procedure carries some risk of injury to vessels and nerves, can lead to lymphedema, and can predispose to a higher complication rate if postoperative RT is needed. Lymphatic mapping (LM) refers to the concept of delineating the path of malignant cells through the lymphatics, identifying the nodes primarily at risk for early spread, and determining if this knowledge will safely allow a limited rather than a complete regional lymphadenectomy.

Thompson and Uren described the sentinel node (SLN) as “any lymph node that receives lymphatic drainage directly from primary tumor” (55). SLN has revolutionized care for women with breast cancer and for those with melanoma. It has also been shown to be of benefit in patients with vulvar cancer. In cervical cancer many reports have shown feasibility and high detection rate of SLN in stages 1A2 to IB. Levenback et al. reported 39 patients with early cervical cancer who underwent RH and PL. Preoperative lymphoscintigraphy was performed, revealing at least one SLN in 85%. Most SLNs were iliac, obturator, and parametrial nodes; however, approximately 20% were in the common iliac and aortic chains. Eight (21%) had nodes involved with tumor, and 5 of these 8 patients had SLN as the only positive node. Sensitivity was 87.5% and negative predictive value (NPV) was 97% (56).

Plante et al. followed with a larger series of 70 patients using laparoscopy. Bilateral SLNs were found in 60% of cases. Using both a gamma probe and blue dye, the SLN detection rate was 93%. Eighty-eight percent of SLNs were in the external iliac, obturator, and bifurcation area. Fifty-one percent had 2 SLNs, and 24% had $\geq$ 3 SLNs. The NPV was 100% and sensitivity was 93%. The rate of allergy to blue dye was 3% (57). Roy et al. studied 211 patients. One SLN was identified in 97% of patients, 16.7% of SLN were in aberrant sites, including about 4% in the paraaortic region. Of the latter group, 15% had a positive node. With ultrastaging the NPV of SLN was 100%, compared with frozen section sensitivity of 94%. The results were best in patients with tumor diameter of less than 2 cm (58). Lecuru et al. studied 139 patients and found at least 1 SLN in 98%. The NPV was 98% but the reliability was significant when bilateral SLN were identified (59). Diaz et al. evaluated their single-institution experience at Memorial Sloan Kettering Hospital and reported a 95% detection rate of SLN. Routine pathologic processing identified 71% of involved SLN with an additional 29% found on ultrastaging (60). Altgassen et al. reported a multi-institutional study of 590 patients, showing a detection rate of 93.5% when blue dye was used in conjunction with technetium-99. The sensitivity was 77% with a NPV of 94% (61).

At the present time, SLN is still investigational and not standard of care in cervical cancer. The overall SLN identification is around 90%, with a sensitivity of 92%, and an approximately 8% false negative rate, with a NPV of 97%. Challenges to adoption include the sensitivity of frozen section, availability of pathologic expertise, uniformity of technique, surgical experience, and clinical impact of tumor size (62).

PATHOLOGY

Squamous Cell Carcinoma

Squamous carcinoma of the cervix includes both microinvasive squamous carcinoma and more deeply invasive carcinoma. Variants of invasive squamous carcinoma, which may be associated with differences in biologic behavior, include verrucous carcinoma, papillary squamous and transitional carcinoma, warty carcinoma, and lymphoepithelioma-like carcinoma.

Preinvasive Disease

Squamous carcinoma *in situ* is a precursor lesion of invasive squamous carcinoma. Squamous carcinoma *in situ* is characterized

FIGURE 21.1. Squamous carcinoma *in situ*. The epithelium displays full thickness atypia. Cells have enlarged, hyperchromatic nuclei, and there is no evidence of maturation.

by full-thickness atypia of the cervical epithelium. Endocervical glands may also be involved. The normal maturation of squamous epithelium is absent. The epithelium is replaced by atypical cells that often have enlarged, oval nuclei and increased nuclear-to-cytoplasmic ratios. Mitotic figures are present. There is no breach of the underlying basement membrane (Fig. 21.1). A recent study of cervical biopsies found excellent interpathologist and intrapathologist agreement in the diagnosis of cervical biopsy specimens (63).

Microinvasive Carcinoma

Microinvasive squamous carcinoma is associated with squamous intraepithelial neoplasia, and may arise from either the surface epithelium or from endocervical glands involved by dysplasia. It is characterized by small nests of cells that have escaped the basement membrane of the surface or glandular epithelium (64). Microinvasive carcinoma often displays cells that are larger, with more abundant eosinophilic cytoplasm than cells in the adjacent dysplasia (Fig. 21.2). A desmoplastic stromal

FIGURE 21.2. Microinvasive squamous carcinoma. There is an area of squamous carcinoma *in situ* (lower left). A nest of invasive carcinoma cells (center) has broken through the basement membrane. The invasive cells are larger, with more abundant cytoplasm and larger, more pleomorphic nuclei. A desmoplastic stroma response is present (right).

reaction is usually present. The nests of microinvasive tumor are irregular and haphazardly arranged. These features are useful in distinguishing microinvasion from rounded, well-circumscribed endocervical glands involved by squamous dysplasia.

DOI should be measured from the basement membrane of the site of origin. If the tumor arises from surface epithelium, depth is the distance from the basement membrane of the surface epithelium to the deepest nest of invasive neoplasm. If the tumor arises from an endocervical gland, depth is measured from the basement membrane of the gland. If the site of origin is not clear, depth is measured from the basement membrane of the surface epithelium.

Nests of superficial invasion seen in small biopsies should be reported as such, with dimensions of the tumor. A diagnosis of microinvasive squamous carcinoma of the cervix requires a LEEP or conization biopsy that encompasses the entire lesion and has negative margins.

Invasive Squamous Cell Carcinoma

Invasive cervical carcinoma arises from high-grade dysplasia that may be detected up to 10 years before invasive carcinoma develops. Untreated squamous carcinoma *in situ* results in invasive carcinoma in about one-third of cases over a period of 10 years. Invasive carcinoma occurs most often after the age of 40 years, although it may be seen in young women. It is associated with human papillomavirus infection in more than 99% of cases. These tumors may consist of firm, indurated masses, or they may be ulcerated or polypoid. Microscopic examination reveals irregular, haphazardly infiltrating nests of cells with eosinophilic cytoplasm and enlarged, atypical, hyperchromatic nuclei (Fig. 21.3).

Mitoses may be numerous, and atypical forms may be present. There is typically a desmoplastic stromal response around the nests of invasive neoplasm. Lymphatic and vascular space invasion may be present, especially in more deeply invasive tumors. Invasive squamous carcinomas are classified as keratinizing or nonkeratinizing, although this classification has no prognostic significance. Keratinizing squamous carcinomas display at least some keratin pearl formation. Nonkeratinizing squamous carcinomas are composed of irregular nests of cells that may display abundant eosinophilic cytoplasm and intercellular bridges, but do not contain keratin pearls. Some squamous carcinomas are composed of smaller cells without evidence of

FIGURE 21.3. Invasive squamous carcinoma. Small, irregular nests of cells with markedly atypical nuclei are present. They are surrounded by desmoplastic stroma, containing inflammatory cells.

neuroendocrine differentiation; these neoplasms should be classified as nonkeratinizing squamous carcinomas.

Invasive squamous carcinomas are also graded (65), although treatment protocols do not depend on grade, and the histologic grade may not correlate with prognosis. Grade 1 (well-differentiated) tumors are not very common in the cervix. They display keratin pearls and large numbers of keratinized cells. Nuclei display only mild to moderate atypia, and mitoses are typically not numerous. Grade 2 (moderately differentiated) tumors represent the majority of invasive squamous carcinomas of the uterine cervix, and are usually nonkeratinizing squamous carcinomas with nuclear pleomorphism, numerous mitoses, and an infiltrative pattern. Grade 3 (poorly differentiated) tumors either have smaller cells without neuroendocrine differentiation, or are pleomorphic with anaplastic nuclei, and sometimes a tendency to form spindle cells that must be distinguished from sarcoma by positive cytokeratin stains.

Variants of Squamous Cell Carcinoma

Basaloid Squamous Cell Carcinoma

Basaloid squamous carcinoma is an invasive, highly aggressive tumor composed of basaloid cells resembling those seen in squamous carcinoma *in situ* (66).

Verrucous Carcinoma

Verrucous carcinoma occurs rarely in the uterine cervix (67). Examination of the cervix reveals a papillary excrescence that may resemble condyloma acuminatum. In fact, lesions termed “giant condyloma of Buschke and Lowenstein” in the past probably represent verrucous carcinomas. Microscopic examination displays papillary fronds of squamous epithelium not containing connective tissue cores. The fronds are often pointed and have a “church spire” appearance. Underlying connective tissue displays bulbous nests of squamous epithelium that invade the stroma with a pushing margin but display little cytologic atypia. Any lesion displaying significantly atypical nuclei does not represent verrucous carcinoma. The distinction between verrucous carcinoma and regular squamous carcinoma is important because verrucous carcinoma invades locally but does not metastasize. In order to diagnose verrucous carcinoma, it is necessary to see the invasive portion of the neoplasm. Superficial biopsies are usually not diagnostic.

Papillary Squamous and Transitional Carcinoma

Some cervical neoplasms are characterized by papillary superficial architecture with substantial nuclear atypia not seen in verrucous carcinomas (68,69). The most common presenting symptoms are vaginal bleeding and abnormal Pap smears. Papillary, polypoid, or granular lesions are often evident upon examination of the cervix.

These tumors have thin or thick papillae that contain connective tissue cores. The papillary processes may be covered by highly atypical epithelium displaying keratinization, or the epithelium may consist of multiple layers of cells with oval, hyperchromatic nuclei that do not show keratinization, and resemble transitional cell epithelium. Nuclear grooves may be present. Some tumors display epithelium with mixed features. Immunohistochemical studies have shown that most of these tumors are cytokeratin 7 positive and cytokeratin 20 negative; these results are consistent with squamous differentiation (69). HPV-16 has been identified in these neoplasms. It has been demonstrated that these tumors all have the same immunophenotype (uroplakin III negative, p63 positive, and p16^{INK4A} positive) regardless of light microscopic features (70). The authors concluded that

these neoplasms lack true transitional cell differentiation and share features with squamous carcinoma.

Many papillary squamous and transitional carcinomas are associated with an underlying invasive carcinoma. The invasive neoplasm is often typical squamous carcinoma, but some cases of invasive transitional carcinoma have been described. Superficial biopsies display only the papillary portion of the neoplasm. LEEP or conization biopsy should be performed to evaluate the possibility of underlying invasive carcinoma.

The invasive form of this neoplasm may be associated with local recurrence and metastasis. These tumors must be distinguished from verrucous carcinomas, which display little atypia and have a much more indolent clinical course.

Warty Carcinoma

Warty carcinoma of the cervix is a rare papillary neoplasm that displays marked condylomatous change but has features typical of routine invasive squamous carcinoma at its deep margin (71). These tumors are associated with HPV and may behave less aggressively than the usual type of invasive squamous carcinoma. Cellular change consistent with HPV infection (“koilocytotic atypia”) is shown in Figure 21.4.

Lymphoepithelioma-Like Carcinoma

Lymphoepithelioma-like carcinoma, more commonly seen in the nasopharynx, also occurs in the uterine cervix. Some patients may present with abnormal bleeding and have cervical masses, whereas others may have abnormal Pap smears and no visible cervical lesions. Lymphoepithelioma-like carcinoma of the cervix is seen most often in Asian women, and it has been associated with Epstein-Barr virus infection in those patients (72). In contrast, studies from Europe have not demonstrated Epstein-Barr virus DNA (73,74), but some have suggested a role for HPV in the etiology of this neoplasm (74–76).

Microscopically, this tumor is characterized by nests of cells with lightly eosinophilic cytoplasm and large vesicular nuclei with prominent eosinophilic nucleoli. Cell borders are indistinct, giving the tumor cell nests a syncytial appearance. Aggregates of tumor cells are surrounded by a prominent inflammatory infiltrate that includes lymphocytes, plasma cells, and varying numbers of eosinophils. This neoplasm can be distinguished from glassy cell carcinoma (which is also accompanied by prominent inflammation) by the lack of prominent cell borders and granular

FIGURE 21.4. Human papillomavirus changes. This squamous epithelium displays cells with large halos surrounding atypical nuclei (“koilocytotic atypia”).

eosinophilic cytoplasm in lymphoepithelioma-like carcinoma. The lymphocytic infiltrate in lymphoepithelioma-like carcinoma of the uterine cervix is predominantly T cell in nature, and most of the T cells are suppressor/cytotoxic CD8 cells (73).

Adenocarcinoma

While the incidence of squamous carcinoma of the cervix has decreased in past decades owing to cytologic screening, the number of cases of cervical adenocarcinoma has increased (77–80). Adenocarcinoma of various types accounts for 20% to 25% of cervical carcinomas (78).

Adenocarcinoma *in situ* (AIS) is a precursor of invasive adenocarcinoma. It is found adjacent to many invasive adenocarcinomas, often accompanied by squamous dysplasia. Both AIS and invasive adenocarcinoma of the cervix are associated with HPV (usually type 18, but sometimes type 16).

AIS is characterized by preservation of the overall endocervical gland architecture. However, endocervical glands and surface epithelium are replaced to varying degrees by cells displaying atypia, including nuclear enlargement and stratification, nuclear hyperchromasia, and mitotic figures (Fig. 21.5). Most adenocarcinomas *in situ* occur near the transformation zone, and skip lesions are unusual (79).

Early Invasive Adenocarcinoma

Early invasive adenocarcinoma of the uterine cervix displays an alteration from the normal endocervical gland architecture (80). This abnormality may take the form of solid or cribriform nests of cells, architecturally irregular or incomplete glands lined by malignant cells, or small buds of highly atypical cells arising from glands involved by AIS. A desmoplastic stroma may be present. Diagnosis of early invasive adenocarcinoma may be difficult because endocervical glands normally have a complex pattern.

The FIGO definition of microinvasive carcinoma applies to all types of carcinoma, but application of this term to glandular lesions of the cervix has not been generally accepted. Some gynecologic pathologists believe that these lesions should be classified as early invasive adenocarcinomas, with a best possible measurement of the DOI (77,79) because an increased incidence of metastatic disease correlates with increasing depth of invasive disease.

FIGURE 21.5. Adenocarcinoma *in situ*. Part of this endocervical gland is normal (upper left corner). The remainder of the gland has been replaced by stratified cells with atypical, large nuclei and mitotic figures.

Mucinous Adenocarcinoma

There are several variants of mucinous adenocarcinoma of the cervix, including endocervical, intestinal, signet ring cell, minimal deviation, and villoglandular variants. HPV DNA has been detected in more than 90% of mucinous adenocarcinomas of the cervix, including endocervical, intestinal, and endometrial subtypes (81).

Mucinous Adenocarcinoma, Endocervical Variant

The endocervical variant of mucinous adenocarcinoma is the most common type of cervical adenocarcinoma. It is composed of irregular, haphazardly arranged tubuloracemose glands lined by cells resembling those seen in normal endocervical glands, although they may sometimes have limited amounts of cytoplasmic mucin. Nuclei are basally located, stratified, and atypical (Fig. 21.6). Mitoses are present. Grade 1 (well-differentiated) tumors have uniform nuclei with minimal stratification and few mitotic figures. Grade 2 (moderately differentiated) adenocarcinomas have more marked cytologic atypia with frequent mitoses. They may also have solid areas accounting for less than half of the neoplasm. Grade 3 (poorly differentiated) adenocarcinomas contain more prominent solid areas, pleomorphic nuclei, and many mitoses. Desmoplastic stromal response is variable in this type of cervical adenocarcinoma.

Mucinous Adenocarcinoma, Intestinal Type, Signet Ring, and Colloid Variants

Rare endocervical adenocarcinomas have glands containing goblet cells; these tumors display intestinal differentiation. Signet ring cell carcinomas and colloid carcinomas are extremely rare and must be distinguished from metastatic tumors from the gastrointestinal tract.

Mucinous Adenocarcinoma, Minimal Deviation Variant

This uncommon tumor represents only about 1.3% of cervical adenocarcinomas (82). Patients range in age from 25 to 72 years. They may present with abnormal bleeding or a mucoid discharge. The cervix may appear normal, or it may display a

FIGURE 21.6. Well-differentiated glands infiltrate desmoplastic cervical stroma. The glands display a haphazard pattern. Nuclei are basally located but stratified and atypical.

firm area or a mass. The neoplasm is very difficult to diagnose on small biopsies because the infiltrative gland pattern cannot be appreciated. Conization specimens are more conducive to accurate diagnosis in this lesion, but some cases have been diagnosed only after hysterectomy. In contrast to most other types of cervical adenocarcinomas, minimal deviation adenocarcinomas are not associated with HPV infection (83).

Gross examination of hysterectomy specimens displays firm, tan-yellow neoplasms. Most cases contain mucinous glands, but some display endometrioid glands. Microscopically, glands infiltrate the cervical stroma in a haphazard manner; they do not conform to the normal endocervical gland pattern. They may display budding contours, and they typically have angular, sharply pointed outlines, in contrast to the rounded contours of benign endocervical glands. The glands of minimal deviation adenocarcinoma appear deceptively benign on low power. Lack of substantial cytologic atypia is a prerequisite for this diagnosis. However, high-power examination reveals at least some areas with mild to moderate atypia, in which some nuclear enlargement, stratification, and rare mitotic figures may be identified. The infiltrating glands may be devoid of any surrounding desmoplastic reaction.

Minimal deviation adenocarcinoma may occur as a sporadic neoplasm, although patients with Peutz-Jeghers syndrome are at risk of developing this cervical tumor.

Mucinous Adenocarcinoma, Well-Differentiated Villoglandular Variant

Well-differentiated villoglandular adenocarcinoma is a type of low-grade adenocarcinoma that displays similarities to villous adenomas of the intestine. Patients may present with polypoid or papillary endocervical masses upon pelvic examination, abnormal bleeding, or abnormal Pap smears. The age range has been 23 to 57 years, with most cases occurring in patients younger than 40 years of age.

Microscopic examination of these neoplasms reveals villous, papillary structures that may be either long and slender, or short and broad. These processes contain a connective tissue core that often displays inflammatory cells. The covering epithelium is a single layer of stratified cells with endocervical, endometrial, or intestinal differentiation. Nuclei display only mild to moderate atypia, and mitotic figures are infrequent (Fig. 21.7). Only tumors with low-grade cytologic atypia should receive this diagnosis,

FIGURE 21.7. Well-differentiated villoglandular adenocarcinoma. Long, slender villous processes are covered with epithelium, displaying mild atypia. Nuclei are crowded, but they retain an oval shape, and are uniform in size.

since other endocervical carcinomas may have papillary features. Invasive adenocarcinoma may be seen deep to the papillary areas, and is characterized by branching glands lined by atypical cells and surrounded by desmoplastic stroma. These neoplasms do not display the marked nuclear atypia and epithelial tufting seen in the much more aggressive papillary serous carcinoma of the cervix. They may be associated with typical AIS of the cervix.

Well-differentiated villoglandular carcinoma has not metastasized unless it was associated with more aggressive types of carcinoma. Some cases have been successfully treated by conization if the tumor is completely excised and the patient wishes to retain fertility. Generally, this diagnosis should not be suggested on the basis of small biopsy specimens; definitive diagnosis should be made only in tumors seen on conization or hysterectomy specimens. Diagnosis of this type of neoplasm on the basis of only a small biopsy specimen could result in undertreatment of a potentially more aggressive neoplasm (78). Villoglandular tumors associated with a high-grade cytologic component or an underlying obvious invasive adenocarcinoma may be associated with lymphovascular invasion, recurrences, and lymph node metastases (84,85).

Endometrioid Adenocarcinoma

Endometrioid carcinomas of the uterine cervix are rare, and have probably been overdiagnosed. These tumors make up about 7% of all cervical adenocarcinomas. These neoplasms display histologic features identical to endometrial carcinoma. Therefore, the possibility of a primary endometrial adenocarcinoma with endocervical extension or drop metastasis must be excluded before the diagnosis of a primary endocervical endometrioid adenocarcinoma is established. A rare case has arisen from endocervical endometriosis. In difficult cases, immunohistochemical stains may be helpful since a combination of CEA positivity, ER negativity, and vimentin negativity is most often seen in endocervical primary tumors, while the reverse is more often characteristic of endometrial primary tumors. Evidence of association with HPV also supports an endocervical primary neoplasm.

Other Adenocarcinomas

Clear Cell Adenocarcinoma

Clear cell carcinoma of the cervix has been associated with intrauterine diethylstilbestrol (DES) exposure; however, it also occurs in the absence of DES exposure. Patients usually have a cervical mass. The solid pattern of tumor displays sheets of cells containing abundant glycogen-rich clear cytoplasm, atypical nuclei, and mitoses. The tubulocystic pattern contains tubules and cystic spaces lined by oxyphilic, hobnail, or clear cells. The papillary pattern is the least common variant and often coexists with solid or tubulocystic areas. Clear cell carcinomas of the cervix are not associated with HPV DNA (83).

Serous Adenocarcinoma

Papillary serous carcinoma of the uterine cervix has a bimodal age distribution, occurring in patients younger than 40 years and patients older than 65 years. This age distribution has also been seen in well-differentiated villoglandular carcinoma but differs from the typical mid-life age of patients with cervical adenocarcinomas in general. Serous carcinomas of the cervix are not associated with HPV DNA (83).

Gross examination may reveal a nodular mass, an indurated cervix, or no visible abnormality. Microscopically, these tumors are identical to serous tumors of the ovary, endometrium, and primary peritoneal serous carcinomas. Considering the rarity with which this type of neoplasm is seen in the cervix, the diagnosis of primary serous carcinoma of the uterine cervix should

FIGURE 21.8. Serous adenocarcinoma. The papillary structures have a connective tissue core. There is marked tufting and stratification, and the nuclei are markedly atypical.

be made only after excluding metastasis or extension of disease from another site, especially the endometrium.

Histologic examination of serous carcinoma of the uterine cervix reveals fibrous papillae lined by atypical epithelial cells; secondary papillae and tufts of neoplastic epithelial cells are often present (Fig. 21.8). Glandular structures have irregular luminal borders due to tufting of tumor cells. Nuclei usually show high-grade atypia, and numerous mitoses are present.

These aggressive tumors may metastasize to pelvic, periaortic, and inguinal lymph nodes. Large and deeply invasive tumors are associated with a worse prognosis.

Mesonephric Adenocarcinoma

Remnants of the mesonephric ducts persist and can be seen in the lateral aspects of the cervix. They are often not identified because uteri are traditionally bivalved along their lateral aspects, and most microscopic sections are taken from the anterior and posterior portions of the cervix. Mesonephric duct remnants are seen as lobules of small, round, glandular structures lined by flattened cuboidal epithelium and containing intraluminal periodic acid-Schiff stain (PAS)-positive material. The cells of mesonephric duct remnants do not contain intracytoplasmic mucin, unlike the cells lining endocervical glands. Mesonephric duct hyperplasia may occur in the cervix. Mesonephric adenocarcinomas are thought to arise from mesonephric duct remnants. Only about 2 dozen cases have been documented (86). Early reports of lesions termed mesonephric carcinoma are now known to represent clear cell carcinoma, with no relationship to the mesonephric duct remnants.

Patients have ranged in age from 52 to 55 years (82). Some patients have not had grossly apparent lesions, but most present with abnormal bleeding and have visible cervical masses. These neoplasms occur deep in the lateral cervical wall. Mesonephric carcinomas display a variety of histologic appearances, including ductal, tubular, retiform, solid, and sex cord-like patterns. Mesonephric hyperplasia may be associated with the carcinoma. Like mesonephric remnants, mesonephric carcinoma tumor cells contain no intracytoplasmic mucin; however, glandular structures may display luminal PAS-positive material. CD10 staining may be useful in diagnosing mesonephric-type adenocarcinomas (87).

Microcystic Endocervical Adenocarcinomas

Eight cases of this type of endocervical adenocarcinoma have been described (88). Most patients presented with either abnormal

Pap smears or vaginal bleeding. Abnormalities of the endocervix were visible in 3 patients. These tumors are characterized by numerous cystically dilated glands simulating the appearance of a benign lesion at low power. However, higher power examination reveals areas of significant cytologic atypia and mitotic activity. Areas of more typical mucinous or intestinal endocervical adenocarcinoma may also be present. These lesions may be deeply invasive. Three patients had significant follow-up data. One patient died after a debulking procedure for a pelvic recurrence 2 years after her initial diagnosis, and 2 other patients are alive without evidence of tumor at 1 and 6.5 years after diagnosis.

Other Epithelial Tumors

Adenosquamous Carcinoma

Adenosquamous carcinoma is a tumor composed of admixed malignant glandular and squamous elements. This term should not be used for poorly differentiated squamous carcinomas, in which mucicarmine stains show only scattered mucin vacuoles. Likewise, it is different from collision tumors, which display adjacent adenocarcinoma and squamous carcinoma. Adenosquamous carcinomas are more commonly associated with higher tumor grade ($p < 0.001$) and vascular invasion ($p = 0.002$) than are adenocarcinomas (89). Adenosquamous carcinomas appear to be either histologically more aggressive or diagnosed at a later stage than adenocarcinomas of the uterine cervix.

Glassy Cell Carcinoma

Glassy cell carcinoma is a rare form of poorly differentiated adenosquamous carcinoma that displays cells with eosinophilic cytoplasm, well-defined cell borders, prominent nucleoli, and a prominent infiltrate of eosinophils and plasma cells. Occasionally, this morphology may be seen in recurrences of adenocarcinomas or adenosquamous carcinomas that have been treated with radiation therapy (78).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma of the cervix is a rare but aggressive malignant neoplasm. These lesions are typically seen in elderly patients, many of whom present with postmenopausal bleeding. Examination of the cervix typically shows a lesion.

Microscopic examination of these tumors reveals a cribriform gland pattern. The glands may contain hyaline or mucinous material. Nuclei are larger and more pleomorphic than those seen in adenoid basal epithelioma, and numerous mitoses as well as areas of necrosis are present in adenoid cystic carcinoma. Electron microscopy has shown basement membrane-like material around the nests of tumor cells as well as in some gland lumina. The tumor cells stain with cytokeratin. In contrast to adenoid cystic carcinoma of the salivary glands, this neoplasm in the cervix has not displayed unequivocal evidence of myoepithelial cells, either by immunohistochemical staining for S100 protein or by electron microscopy.

Adenoid cystic carcinoma of the cervix often recurs. It may metastasize. Patients with advanced stage disease have a poor prognosis.

Adenoid Basal Epithelioma (Carcinoma)

Adenoid basal epithelioma is a rare cervical neoplasm. It was originally called adenoid basal carcinoma. The indolent behavior of most of these neoplasms led to the term “adenoid basal epithelioma.” More recently, Parwani et al. reported 10 tumors that had low-grade adenoid basal epitheliomas admixed or associated

with invasive carcinomas of various types, including adenoid basal/squamous carcinoma, pure squamous carcinoma, adenoid cystic carcinoma, or small cell neuroendocrine carcinoma. Most adenoid basal epitheliomas and associated invasive carcinomas contain HPV-16 DNA. It now appears that adenoid basal epitheliomas may be precursor lesions that may give rise to carcinomas of various types. These tumors should now be subclassified as adenoid basal epitheliomas and carcinomas (90).

The age of patients with adenoid basal epithelioma ranges from 30 to 91 years (82). This neoplasm is often seen in postmenopausal women who are asymptomatic, with normal appearing cervixes. These lesions are usually incidental findings in specimens obtained for the purpose of evaluating squamous intraepithelial neoplasia. A neoplastic squamous component is often an associated feature (82).

Microscopically, adenoid basal epithelioma is characterized by nests of cells that have a basaloid appearance, and may display peripheral palisading. Some gland lumina are present in the basaloid cell nests, although the number of glands is variable. Squamous metaplasia may also be seen. Mitotic figures are typically rare.

Adenoid basal epithelioma, in the absence of a coexisting invasive carcinoma, is a benign lesion with no reported cases of metastatic behavior (82). It must be distinguished from adenoid cystic carcinoma, which is an aggressive malignant neoplasm. Adenoid basal tumors with carcinomatous components should be reported as carcinomas.

Neuroendocrine Tumors

Standardization of terminology for neuroendocrine tumors of the uterine cervix (91) has facilitated evaluation of the incidence and biologic behavior of these neoplasms. Immunohistochemical (chromogranin and/or synaptophysin stains) evidence of neuroendocrine differentiation is necessary for diagnosis of all neuroendocrine tumors except small cell carcinoma.

Typical Carcinoid Tumors

Typical carcinoids of the cervix are rare neoplasms. This diagnosis should be made with caution, because most cervical neuroendocrine tumors are aggressive neoplasms. There are not enough documented cases of this neoplasm to permit assessment of biologic behavior.

Atypical Carcinoid Tumors

Atypical carcinoid tumors display organoid nests of cells, but the cells display nuclear atypia and a mitotic rate of 5 to 10 MF/10 HPF. Necrosis may be present. These tumors are also rare, precluding evaluation of biologic behavior.

Large Cell Neuroendocrine Carcinoma

Large cell neuroendocrine carcinomas (Fig. 21.9) display organoid nests of cells with peripheral palisading of nuclei, prominent nucleoli, variable amounts of necrosis, eosinophilic cytoplasmic granules, and numerous mitotic figures (>10 MF/10 HPF). Vascular/lymphatic space involvement is often seen, and many of these tumors are associated with coexisting AIS or adenocarcinoma of the cervix (92). These tumors are highly aggressive neoplasms (93). Evidence of neuroendocrine differentiation is necessary for diagnosis and is most easily obtained with immunohistochemical stains for chromogranin and synaptophysin.

Small Cell Carcinoma

Most neuroendocrine tumors seen in the uterine cervix represent small cell carcinomas. Even a small component of small cell carcinoma in a tumor of mixed type is associated with adverse

FIGURE 21.9. Large cell neuroendocrine carcinoma. This tumor displays organoid architecture. The tumor cells are much larger than those seen in small cell carcinoma. They have abundant eosinophilic cytoplasm, and there are numerous mitotic figures. Areas of necrosis were present elsewhere in the tumor.

outcome (93). Small cell carcinoma is characterized by cells with scant cytoplasm, inconspicuous nuclei with finely stippled chromatin, nuclear molding, extensive necrosis, crush artifact, and numerous mitotic figures (Fig. 21.10). Single-cell infiltration of the stroma is common. Vascular/lymphatic space invasion is often seen.

Mixed Epithelial and Mesenchymal Tumors

Müllerian adenosarcomas occur in the cervix (94). Patients may present with abnormal bleeding. These neoplasms consist of polypoid or papillary masses. Microscopically, they display benign glands and sarcomatous stroma with a periglandular cuff of condensed stroma. The sarcomatous component contains variable numbers of mitotic figures, and some cases display heterologous elements including cartilage and striated muscle. These tumors generally have a favorable prognosis, but deep invasion and sarcomatous overgrowth are adverse prognostic factors.
